PROPERTIES OF PLEISTOCENE SEDIMENT IN TWO WELLS IN THE WEST-CENTRAL PORTION OF THE BIG LOST TROUGH, EASTERN SNAKE RIVER PLAIN, IDAHO NATIONAL LABORATORY, IDAHO

by

Christopher M. Mudge

A thesis

Submitted in partial fulfillment

of the requirements for the degree of

Master of Science in the Department of Geosciences

Idaho State University

Summer 2016

Committee Approval

To the Graduate Faculty:

The members of the committee appointed to examine the thesis of Christopher M. Mudge find it satisfactory and recommend that it be accepted

Paul Karl Link
Major Advisor

Glenn Thackray
Committee Member

Robert Watkins
Graduate Faculty Representative

Acknowledgements

I would like to thank Roy Bartholomay and Mary Hodges of the USGS for both giving me the opportunity to complete a masters at Idaho State University, and guiding me through the thesis and providing me insight along the way. My thesis was supported by a research assistantship funded by the USGS.

I would also like to thank Bruce Finney and Mark Shapley for letting me prepare my grain size samples in their laboratory.

Finally I would like to thank Glenn Thackray and Paul Link for their guidance and ever helping hands during the thesis process, allowing me to be successful at Idaho State University.

Abstract

Sediment in cores from drillholes Naval Reactor Facility (NRF) 15 and United States Geologic Survey (USGS) 142 from the northern part of the Big Lost Trough (BLT) at the Idaho National Laboratory (INL) document an evolution of facies during Early Pleistocene time. Although more than 95% of the upper portions of these cores is basalt, sedimentary intervals, from 520 ft to 595 ft below land surface (BLS) in NRF 15 and from 732 ft to 837 ft BLS in USGS 142 were analyzed for grain size and petrologic analysis. The large difference in depth BLS between USGS 142 and NRF 15 is accounted for by variable subsidence across the BLT. Estimated ages, based on paleomagnetic signatures of the basalt, suggest that the intervals are 884 ka-988 ka. Each interval consists of clay that grades upward to coarse silt and sand. Through grain size analysis and visual inspection of the core each interval is interpreted to represent a lake that shallows upward into shoreline sands and loess.

Three depositional environments can be interpreted from the grain size data in each of these upward coarsening intervals. The lower part of each interval is clay dominated and coarse-skewed with average grain-size of 6 to 8 phi. This interval is interpreted as a shallow lake deposit. The intervals then coarsen upward to a fine-skewed silty sand, interpreted as shoreline or eolian sediment. Parts of the upper portions of sedimentary intervals in NRF 15 display bimodal grain size distributions with peaks at 2 and 8 phi; this sediment is interpreted as loess.

Point counting reveals that sands in the shoreline facies are volcanic lithic arenites (58% lithics, and of those 63% are volcanic lithics with 54% of the volcanic lithics being felsitic volcanic grains). These sands are interpreted to reflect transport via the paleo-Big Lost River, and are most likely sourced from the Challis volcanics, which are primarily dacitic and rhyodacitic in composition. The detrital zircons in the sandy intervals at 840 and 780 feet in USGS 142 resemble samples previously described from the Big Lost River. The zircon age spectra have an age peak at 45 Ma that correlates most closely with a Challis volcanic source, and a

Neoproterozoic age peak at 675 Ma that correlates with granitic rocks intruded into the Pioneer Mountains core complex.

Chapter 1

1.1 Introduction

Extensive Pleistocene lakes have formed repeatedly on the Eastern Snake River Plain (ESRP); resulting from the interplay of regional and local subsidence, volcanic activity, and climatic fluctuations (Anderson, 1991; Anderson and Bowers, 1995; Bestland et al., 2002; Geslin et al., 2002). Researchers have studied the timing and extent of sediment deposits on the ESRP and inferred the presence of lakes, playas, and fluvial deposits (Anderson, 1991; Anderson and Bowers, 1995; Gianniny et al., 1997; Blair, 2002; Bestland et al., 2002; Geslin et al., 2002; Mark and Thackray, 2002). This study focuses on identifying three depositional environments in two cores that have been drilled in the Big Lost Trough (BLT) within the Idaho National Laboratory (INL) (Fig. 1). The two cores, USGS 142 and NRF 15, are the focus of the investigation, chosen because they have not yet been significantly studied and have proximity and correlative potential to each other. The investigation of these cores seeks to clarify subsurface locations of lacustrine, loess, and shoreline sedimentary deposits across the west-central part of the INL, and to extend knowledge of the subsurface stratigraphic architecture of the Big Lost Trough (BLT) (Fig. 1).

1.1.1 Flow Group Labeling

Paleomagnetic inclination and polarity studies provide age constraints and correlation for basalt intervals within the INL (Champion et al., 2011; Champion et al., 2013; and Champion, D. E., USGS, 2015 unpublished data). Basaltic flow groups are named based on the source vent, so the material in flow group North Late Matuyama all came from the same vent, and was emplaced in the same effusive eruption. The term “North Late Matuyama” refers to “north” or “south” based on vent location on the INL, and “Late Matuyama” refers to the upper part of the Matuyama interval, below the Bruhnes interval (Hodges et al., 2012) An eruption can last days to decades. Each flow group also has similar paleomagnetic inclination values; this allows for basalt

in core holes to be correlated, when a definite location of the vent is unknown (Champion et al., 2011).

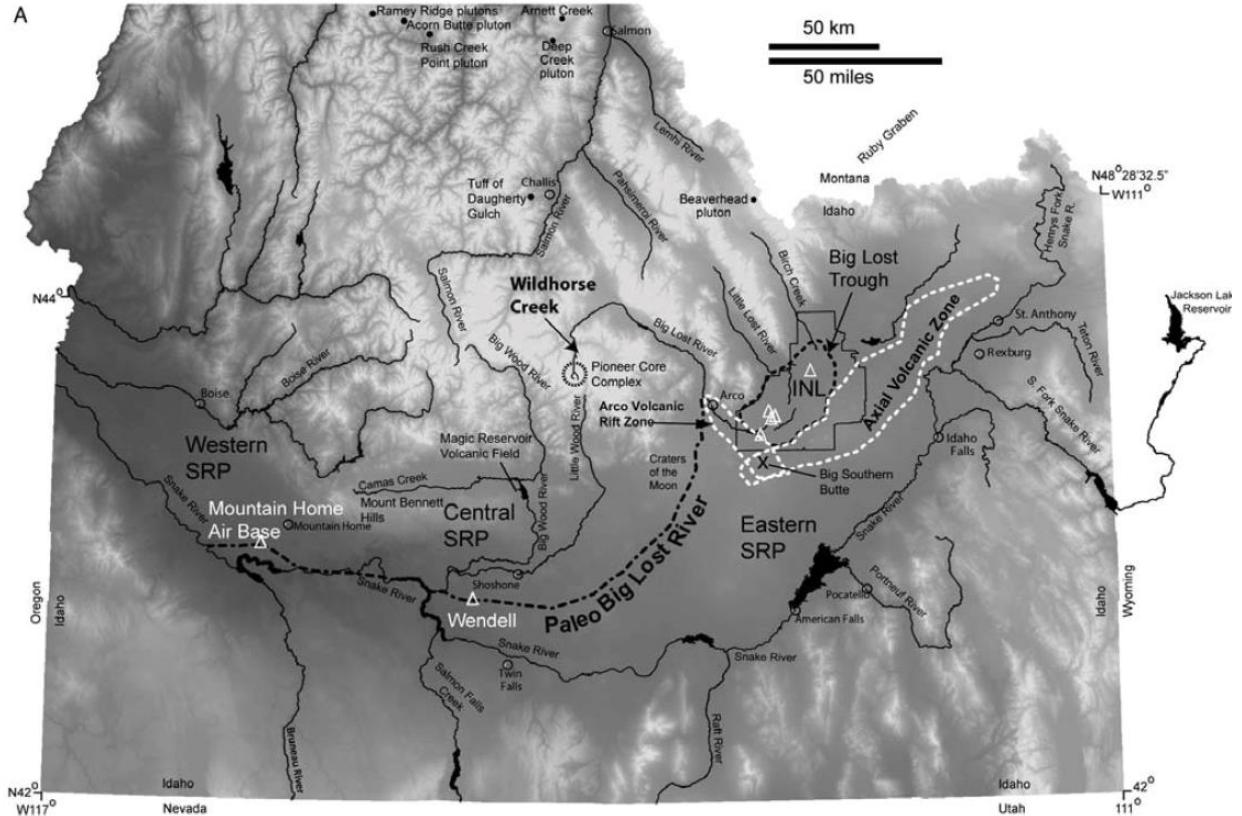

Figure 1: Map of southern Idaho, note the location of the Eastern Snake River Plain, Idaho National Laboratory, the Axial Volcanic Zone, Pioneer core complex, and the paleo Big Lost River (the location of the Big Lost River 3 to 5 Ma). Basin and Range structures are located just north of the Big Lost Trough (BLT), the location of USGS 142 and NRF 15 is in the western portion of the INL and BLT (from Hodes et al., 2009).

This paper provides information about the timing of sedimentary deposits, through the use of paleomagnetic studies. The work done by Duane Champion is used to assign ages to sediment intervals in USGS 142 and NRF 15, and is a basis for the correlation of selected intervals across the west central part of the INL. Age dating studies (Champion and Lanphere, 1997; Hodges et al., 2015) and correlative paleomagnetic studies by Champion et al. (2013) indicate the timing of the sedimentary deposits studied in this thesis to be about 884 ka-988 ka

(North late Matuyama to Jaramillo) Fig. 2; these ages correlate to sediment deposited during Marine Isotope Stage (MIS) 22-25, spanning at least one glacial-interglacial cycle during Early Pleistocene time (Lisiecki and Raymo, 2005).

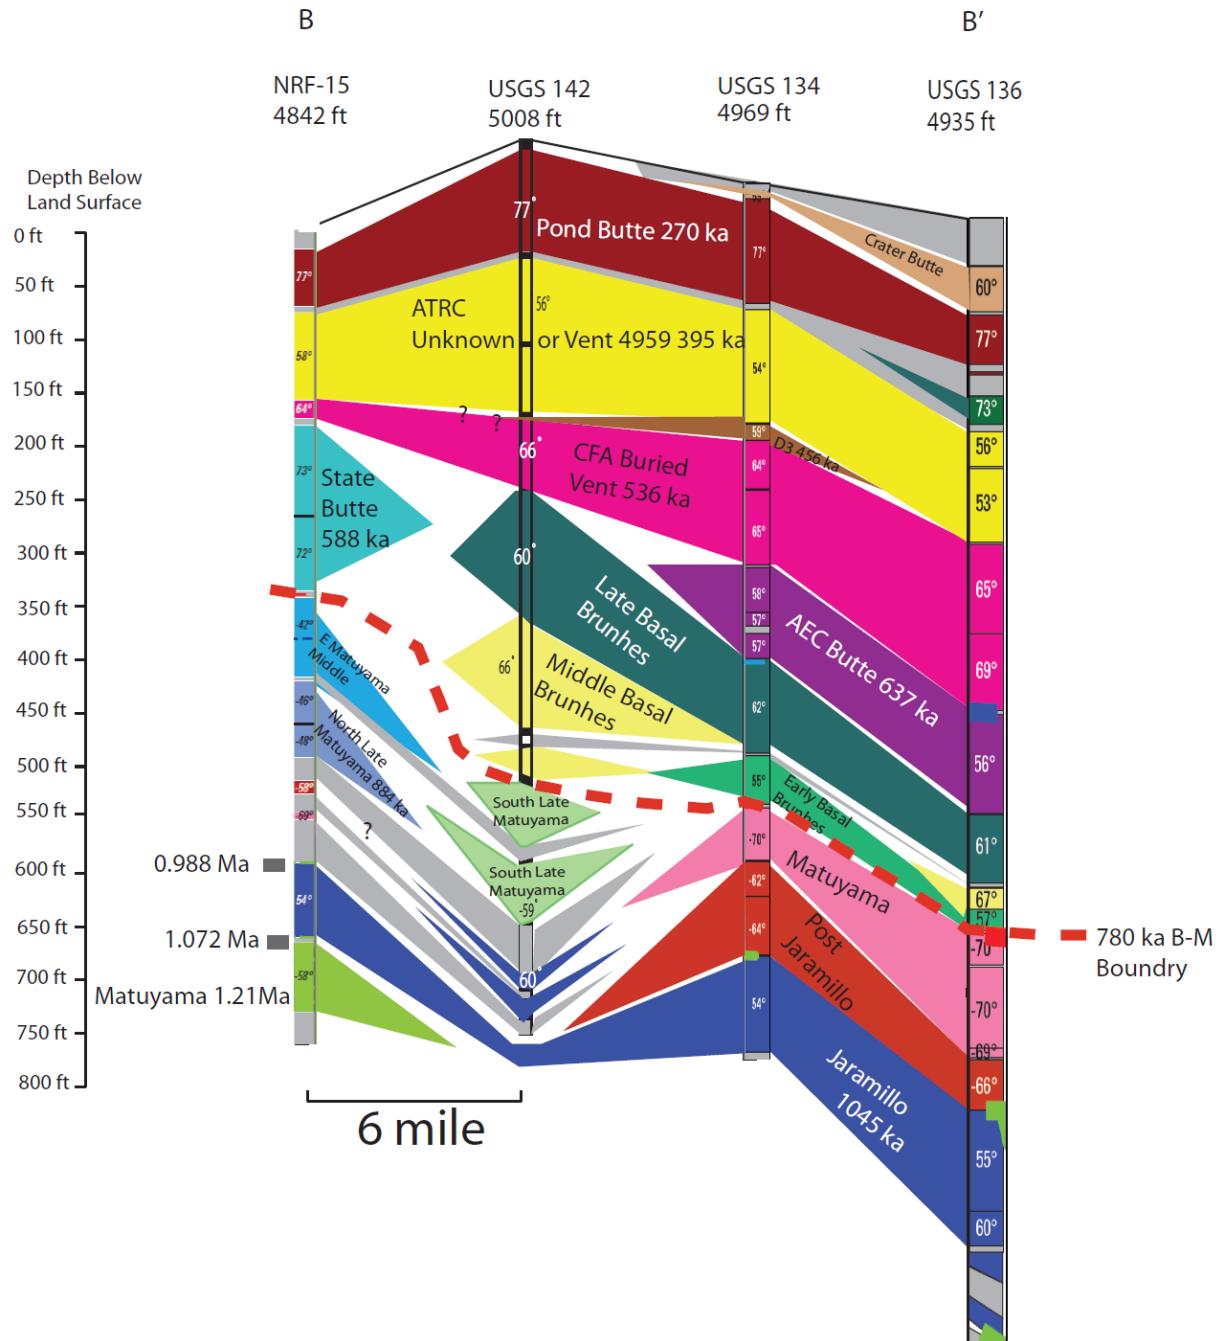

Figure 2: Fence diagram showing the age and distribution of basalt and sediment deposits found between core holes, NRF 15, USGS 142, USGS 132, and USGS 136. The question marks are unknown basaltic ages. The units in grey are the sediment intervals. The red dotted line represents the Brunhes Matuyama boundary (780 ka). The numbers in each hole represent average inclination values for that flow group (Redrawn from Champion et al. 2013 data and Mary Hodges written communication 7/20/2016). Correlations were made by interpretations by Mary Hodges and Duane Champion.

This thesis will characterize the deposition of sediment deposits in these two core holes lying in the west-central part of the INL. Subsidence in the BLT is 124 meters (656 feet) from 350-247 thousand years ago (Wetmore, 1998). Subsidence along with lake base level change, induced by volcanic damming, can create accommodation space for the deposition of surficial sediment in the BLT. Climate change and base level change are the cause for small scale cycles seen in the BLT, and account for the cycles identified in correlated intervals in this thesis.

Several techniques are used in this thesis to determine environmental change. Grainsize distributions, skewness, and sorting are used to determine sediment properties. Detrital zircon geochronology and point counting are used to determine the provenance of coarser grained sediment. Hydraulic conductivity values, derived from grain-size analyses, help understand aquifer properties in the upper part of the eastern Snake River Plain aquifer. The combination of all of these properties allows for a more complete hydrologic model of the subsurface in the west central portion of the BLT.

1.1.2 History

The US Atomic Energy Commission, which later became the Department of Energy, established the National Reactor Testing Station (NRTS) in 1949 for the use of atomic energy projects. The site went through several name and mission changes before being named the Idaho National Laboratory (INL) in 2005. The Idaho National Laboratory (INL), operated by the U.S. Department of Energy (DOE), encompasses about 890 mi² of the eastern Snake River Plain in southeastern Idaho (Figure 3). The INL was established in 1949 to develop atomic energy, nuclear safety research, defense programs, environmental research, and advanced energy concepts. More recent work has focused on spent nuclear fuel management; hazardous and mixed waste management and minimization; national security; cultural resources preservation; and environmental engineering, protection, and remediation (Bartholomay et al., 2002).

The (USGS) has been involved with the site since 1949, conducting groundwater quality studies and water level measurements; which are meant to track contaminant plumes, resultant from management of radioactive waste (Bartholomay et al., 2002). Continual work by the USGS includes improving upon the stratigraphic understanding of basalt and sediment that comprise the ESRP aquifer to assist with understanding groundwater flow (Roy Bartholomay, USGS, written commun. 7/13/2015). This thesis was funded by the USGS by a grant to further the stratigraphic understanding of the Big Lost Trough.

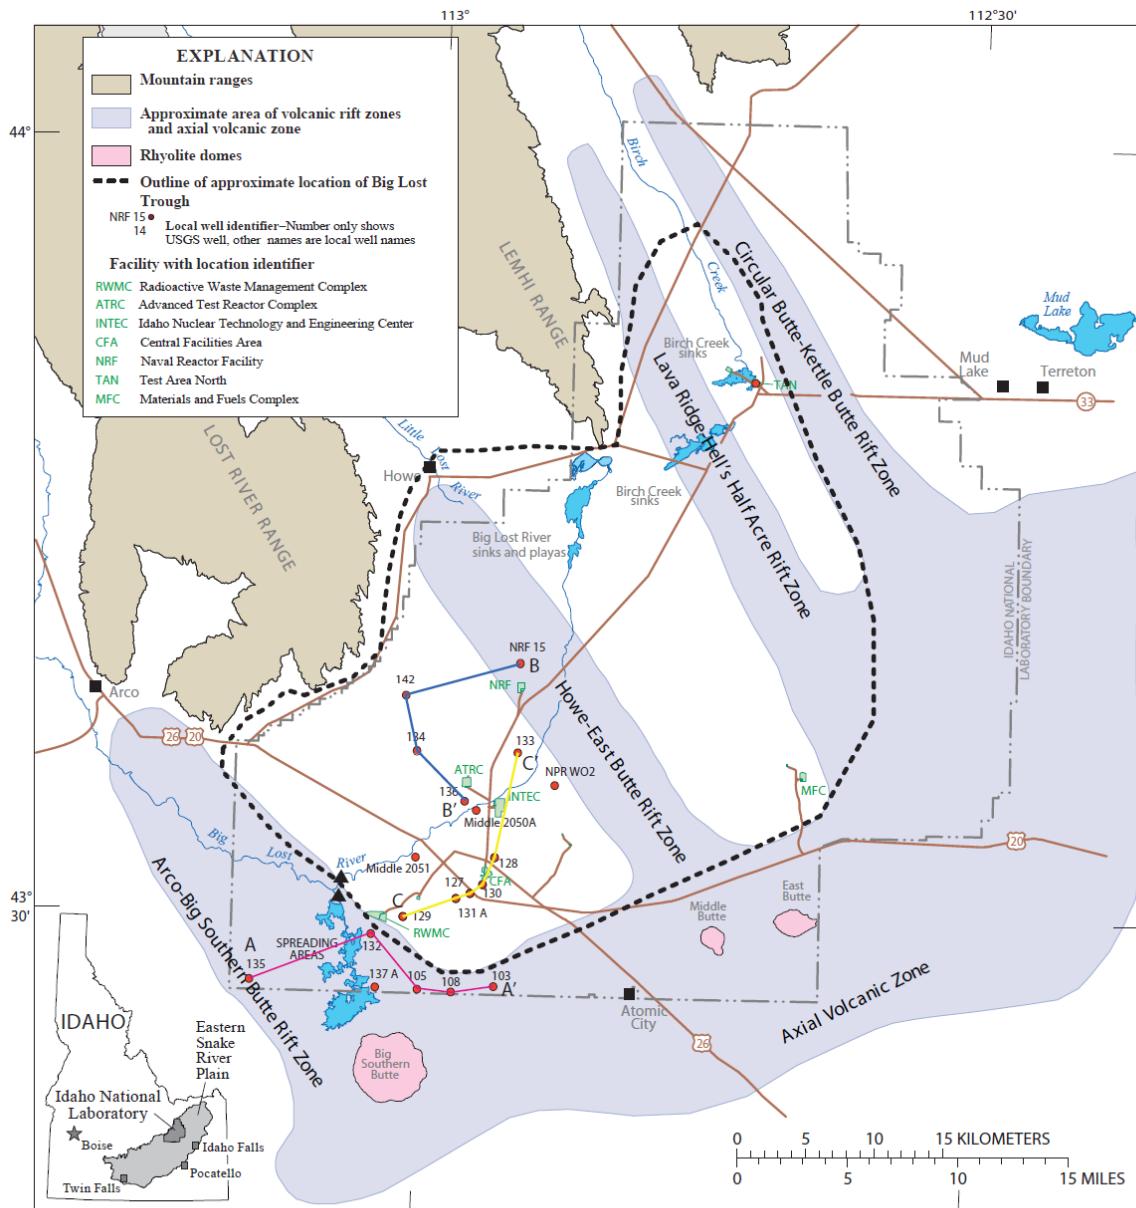

Figure 3: Map of the Idaho National Laboratory (INL). The Big Lost Trough is outlined in black dashes; the holes of interest USGS 142 and NRF 15, and the location of cross section B and B' are shown (from Twining et al., 2012).

1.2 Geologic Setting

1.2.1 Eastern Snake River Plain

The ESRP is a northeast-trending basin about 200 mi long and 50 to 70 miles wide, and is a seismically quiescent, low relief region located across south central Idaho (Anderson and Bowers, 1995; Pierce and Morgan, 1992; Geslin et al., 2002). The plain is dominated by basaltic lava flows, rhyolitic domes, fluvial deposits, seasonal playas and discontinuous loess. Modern Basin and Range extension occurs north and south of the Snake River Plain. Shortening prior to Basin and Range deformation is represented by Cretaceous to Paleocene Sevier deformation (Geslin et al., 2002; Weil and Yonkee, 2012).

The ESRP has existed for some 10 million years (Morgan, 1972; Armstrong et al., 1975). This is represented by the movement of the North American Plate over a stationary mantle plume (Yellowstone Hotspot). The ESRP contains older rhyolite calderas overlain by basaltic material. Chemical analysis of basalts show a sub-lithosphere mantle plume origin, similar to Hawaiian Island basalts (Morgan, 1972; Armstrong et al., 1975; Geist et al., 2002; Shervais and Hanan, 2008). Explosive, caldera-type silicic volcanism occurred on the ESRP from approximately 10 to 4 Ma and moved to the northeast as North America moved to the southwest (Pierce and Morgan, 1992). The mantle plume is now located under the Yellowstone plateau (Yuan and Dueker, 2005; Waite et al., 2006; Pierce and Morgan, 2009).

1.2.2 Hotspot volcanism

The Yellowstone “hotspot” hypothesis revolves around work done by Morgan (1972); Armstrong et al. (1975); Pierce and Morgan (1992); Smith and Braile (1993); Camp (1995); Camp and Hanan (2008); Shervais and Hanan (2008). They argue that a stationary plume originating 16 Ma, in the location where Oregon, Nevada and Idaho meet, formed the Owyhee-Humboldt Volcanic Field, and is the source of magmatism across the Snake River plain.

Continued movement of the North American plate to the south-west allowed for multiple successive eruptive centers in the last 16 m.y. These eruptions are large and siliceous, with the most recent eruption approximately 600 ka under the Yellowstone Plateau in Wyoming. This magmatism created the Heise Volcanic field, 6 to 4 Ma, and products of this magmatism underlie the current sediment and basaltic material found across the INL.

1.2.3 Big Lost Trough

The study area is located within the Eastern Snake River Plain (ESRP) (Fig. 1, Fig. 3), and completely within the Big Lost Trough (BLT) (Fig. 3) an underfilled, volcanically silled basin. The BLT is found directly north of the Axial Volcanic Zone and south of Basin and Range structures. Volcanic features bounding the BLT are Lava Ridge-Hell's Half Acre and the Circular Butte- Kettle Butte volcanic rift zones to the north-east and the Arco-Big Southern Butte volcanic rift zone to the southwest. Surficial deposits within the BLT are fluvial, eolian and playa sediment. The area has become variously lacustrine dominated and eolian dominated multiple times during the Holocene, seen as Lake Terreton highstands and lowstands (Kimmel, 1982; Gianniny et al., 1997; Geslin et al., 1999; Blair, 2002; Mark and Thackray, 2002). Surficial ages of sediment and basalt within the BLT range from 940 ka to the north to 15-200 ka to the south (Geslin et al., 1999).

1.2.4 Modern Sedimentation

Lakes have formed repeatedly throughout the Pleistocene within the Big Lost Trough (BLT). The BLT sub-basin is defined by the terminus and sedimentation from the Big Lost River, Little Lost River and Birch Creek, and is found completely within the INL boundaries (Fig. 3). Olduvai Lake, Diamictic Lake, and Lake Terreton represent fine grained facies deposited in the BLT during the Pleistocene (Bestland et al., 2002; Geslin et al., 1997).

Modern sedimentation results in the development of ephemeral lake beds with dunes and lunettes, bounded by volcanic rift zones, which are areas defined by basaltic vent material, and

are parallel to Basin and Range structures (Geslin et al., 1997). The basalt from various rift zones fill in the topographic lows, directing the location of future sedimentation across the BLT. Surficial deposits represent active sedimentation into the INL (Geslin et al., 2002; Mark and Thackray, 2002), but because of late Holocene drying, perennial playas and sinks now form the terminus of the Big Lost River, Little Lost River and Birch Creek, and all other bodies of water that flow into the BLT.

1.2.5 Correlation of Flow Groups

Samples were collected from both surface sites and from core, and analyzed by Duane Champion. Inclination and polarity was calculated and then averaged for each flow group. These averaged values were then assigned a name based on similar polarity values. Flow groups can contain more than a dozen individual flows from the same eruptive event Fig. 2. The correlation of material between holes is based on of the mean inclination values and location of the flow group in the hole. Correlation of material over long distances is difficult because flows pinch out and have low relief (Champion et al., 2011).

Paleomagnetic correlations were reconstructed using data produced by Mary Hodges and Duane Champion (written communication 7/20/2016). The results or these reconstructions can be found in Fig. 2, and allow for the dating of sediments intervals found in USGS 142 and NRF 15. Basaltic flow units are named by which vent the basalt is sourced from, an example of this is Pond Butte. All the basalt sourced from Pond Butte has similar paleo magnetic values and stratigraphic location in the subsurface, and is assigned an age of 270 ka based on dating techniques.

Chapter 2

2.1 Methods

Stratigraphic and sedimentological properties were used to better understand sediment found at depth in two cores found in the BLT, NRF 15 and USGS 142. A combination of detrital zircon ages and point counting were used to determine the source and provenance of sediment. Hydraulic conductivity was estimated to quantify aquifer properties.

In this thesis, English units are used because that is how depths are measured on the drill cores at the INL. In some places both US customary measurement system and metric units are reported. This was done so the data are more acceptable to a wider audience.

2.1.1 Smear Slides (Appendix A)

Smear slides provide a relatively low cost and efficient means of observing the general sediment composition in sedimentary intervals sampled. Slides were made by wetting and disaggregating sediment samples so they could be easily placed on glass slides using an eye dropper. One to two drops of sediment, for each sample, are placed onto the slide before it is heated. Once heated a slide cover is overlain. Each heated slide and cover pair were injected with ultra-violet (UV) reactive glue and placed under a UV light to permanently affix the slide cover. Using a binocular microscope general descriptions of grain size, overall composition, and rounding were made. Information obtained through this method is used to evaluate what further preparation methods were needed. Samples taken from cores USGS 142 and NRF 15 displayed concentrations of secondary calcium carbonate requiring acid washing as detailed above. To identify minerals and composition of material found in the smear slides, the Tool for Microscopic Identification on the LacCore web site at the University of Minnesota (<https://tmi.laccore.umn.edu/>, Mark Shapley verbal communication 10/12/2015) was used. Smear slides here were only used to assign preparation methods.

2.1.2 Hydraulic Conductivity Method (Appendix B)

Sediment hydraulic conductivity was estimated using mean grain size and textural maturity (Shepherd, 1989; Fetter, 2001). Microscope examination combined with sorting values provides a means of assigning samples a textural maturity within the consolidated sediment characteristic curve (Fig. 4) (Shepherd, 1989). Hydraulic conductivity is then calculated using the following equation (Brian Twining, USGS, written communication Apr 12, 2016):

$$K = c(D_{50})^j$$

K = Hydraulic conductivity

c = The shape factor-dimensionless, determined from textural maturity, in this case a value of 100 is used because of poorly sorted, angular sediment, found through microscope work

j = is an exponent again based on sedimentary properties (poorly sorted and angular grains) here it is 1.5

D_{50} = The mean grain size of the sediment sampled

2.1.3 Loose sediment slides (Point Counting Appendix C)

Sediment samples for point counting analysis were sent to Wagner Petrographic. While at Wagner Petrographic slides were mounted and polished allowing for identification of sediment grains using a Nikon Optiphot polarizing microscope fitted with a Hacker Instruments Automatic Point Counter Model F. The following groups of grains were used for point counting: mono-crystalline quartz, poly-crystalline quartz, feldspar, biotite, chert, Quartz-mica-feldspar (Qmf) aggregates, felsitic textured volcanic lithics, lathwork volcanic lithics, microlitic-textured volcanic lithics, siltstone sedimentary lithics, and carbonate sedimentary lithics.

Point count results were plotted in a Standard QFL (quartz-feldspar-lithic) diagram (Dickinson, 1985), and the QtLsLv (quartz total, sedimentary lithic, and volcanic lithic) diagram (Weltje, 2006). QtFL was used in preference over the QmFL, a plot that characterizes poly-crystalline quartz as a lithic, because there were not enough poly-crystalline quartz grains to change the results of the overall plot. Point counts were also compared with grain size distributions. This determined if the mineralogical maturity of samples created change in the sorting of sediment.

2.1.4 Grain Size Analysis (Appendix D)

Samples were collected from two cores on the INL, USGS 142 (732-837 ft BLS) and NRF 15 (520-595 ft BLS), location of these cores can be found in Fig. 2.

At the geochemical preparation lab, Idaho State University, samples were acid washed with 1 molar HCl as treatment for calcium carbonate. Samples were then neutralized through repetitive centrifuge/decanting stages using high purity deionized water. Prior to and after the acid wash steps the weight of each sample was measured. Acid washing is conducted to eliminate secondary calcite that would affect grain size results. A small amount of high purity deionized water was left in each sample, this allowed for a paste to be formed just prior to analysis, giving an even mix and a proper representation of sediment distribution for each sample. Loose sediment, previously treated for calcium carbonate, was dried prior to grain size analysis.

Grain size analysis were completed at the stable isotope laboratory at Utah State University, on a Malvern instrument Mastersizer 2000 Laser Particle Size Analyzer. The purpose of this analysis was to better understand grain size distributions in the selected sedimentary intervals. The Malvern uses obscuration of a detecting surface to determine grain size, then represents grain sizes in bins of a certain grain size interval. The final data is presented in an Excel file as percentages of each grain size interval detected.

Grain size data were used for determining sorting and skewness (appendix B) calculations from the formulas (Folk and Ward, 1957):

$$\text{Sorting- } \sigma\Phi = \frac{(\Phi_{84} - \Phi_{16})}{4} + \frac{(\Phi_{95} - \Phi_5)}{6.6}$$

$$\text{Skewness - SK} = \frac{\Phi_{16} + \Phi_{84} - 2\Phi_{50}}{2(\Phi_{84} - \Phi_{16})} + \frac{\Phi_5 + \Phi_{95} - 2\Phi_{50}}{2(\Phi_{95} - \Phi_5)}$$

2.1.5 Detrital Zircon Geochronology and Provenance (Appendix E)

Two samples were collected from USGS 142 for detrital zircon analysis, to determine the depositional source area for what is identified as fluvial reworked sediment. USGS 142 core site is located 6 miles west of the Naval Reactors Facility, NRF site on the INL, and is part of the BLT (Fig. 2) Two kilograms (4.4 pounds) for each detrital zircon sample were taken for analysis, DZ2 at a depth of 780 ft in core hole USGS 142, and DZ1 at a depth of 832 ft in core hole USGS 142.

Samples were processed by Multiple Collector Laser Ablation Inductively Coupled Plasma Mass Spectrometry (MC-LA-ICP-MS) on a Thermo Element2 single-collector ICPMS, at the Arizona Laserchron Center, University of Arizona. Processes completed at the Laserchron center include sample preparation, and mineral separation, along with mass spectrometry analysis. Uranium-Thorium- Lead (U-Th-Pb) decay rates, were used to age date the formation of selected zircon grains; a technique known as geochronology. Geochronology, through the use of U-Th-Pb decay acts like a barcode on commercial products (Link et al., 2005), and gives a good understanding of where sediments were originally sourced. Ages of zircon grains were found from the weighted mean of $^{206}\text{Pb}/^{238}\text{U}$, $^{207}\text{Pb}/^{235}\text{U}$, and $^{208}\text{Pb}/^{232}\text{Th}$ -correted ages, using the NUagecalc Excel macros and the Isoplot plugin (Ludwig, 2003) for Excel. Statistical similarity of the samples provenance was determined using a two sample Kolmogorov-Smirnov test, using an Excel macro obtained from the University of Arizona Laserchron Lab (Guynn and Gehrels,

2010). The use of MC-LA-ICP-MS allows for the dating of individual grains. In the case of this study we are identifying the source of fluvial sands and silts deposited in the BLT.

2.1.6 Stratigraphic description

Core descriptions were made using USGS Corelogger program (Davis et al., 1997) as described at <http://id.water.usgs.gov/INL/Facility/C-S-L/index.html> (accessed on May 9, 2016). These descriptions identify aspects of the sediment not captured by other methods (e.g. observations of bioturbation, plant remains/traces, etc.).

The methods introduced in this section will be used to interpret the sedimentary environments that previously existed on the Snake River Plain. Mark and Thackray (2002) used a similar approach of using grain size analyses, skewness, sorting and mean grain sizes along with hydraulic conductivity to assign properties to surficial samples of known sediment facies at the INL.

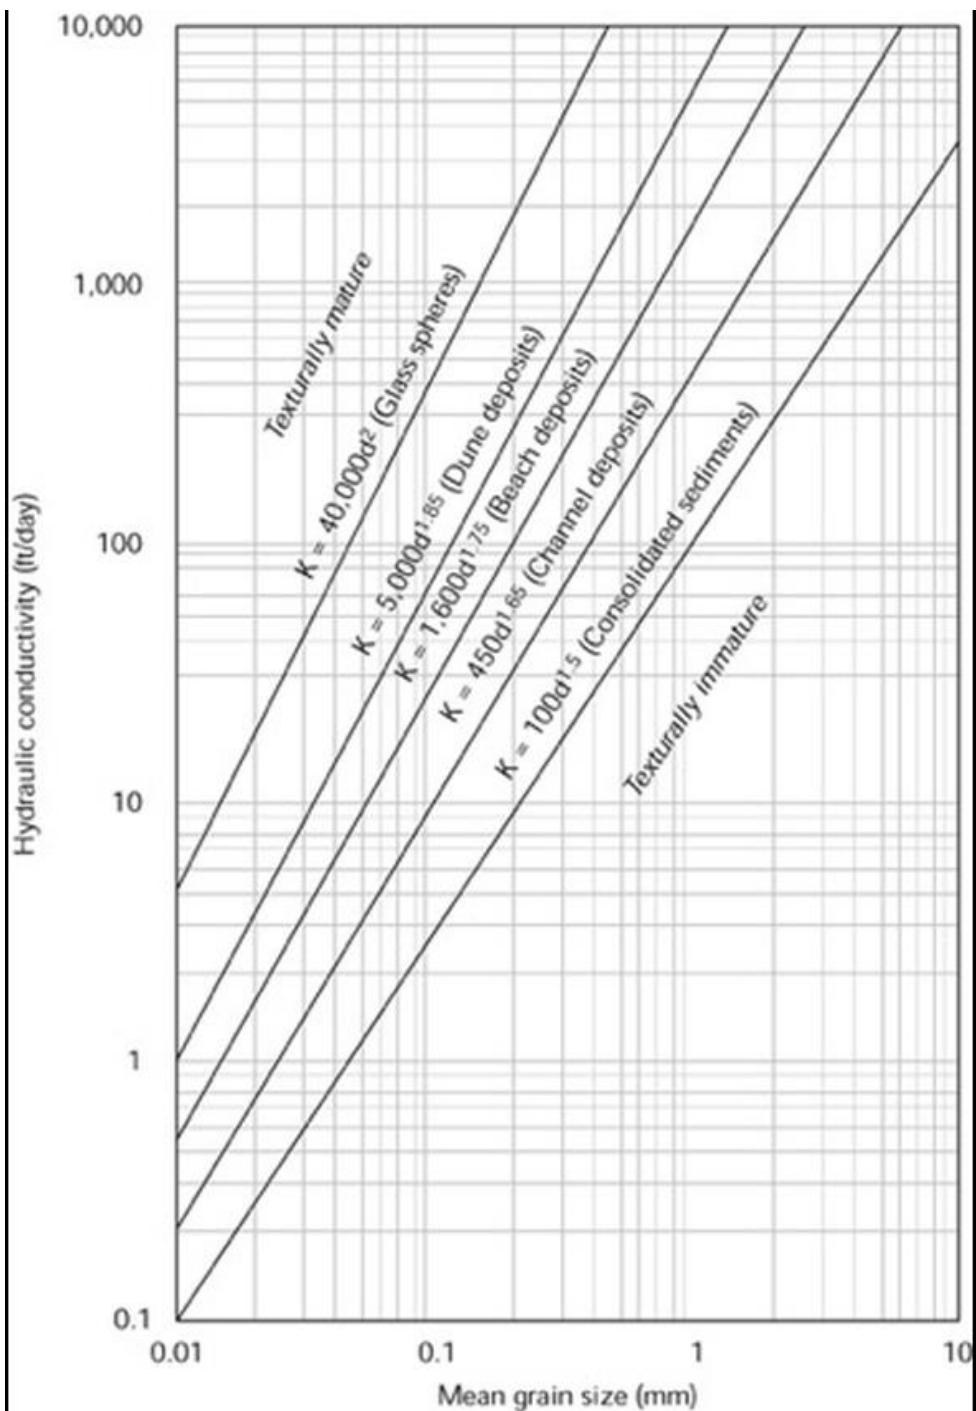

Figure 4: Graph used to determine Hydraulic conductivity from Fetter (2001).

2.2 Previous Environmental Interpretation

Previous environmental interpretation of sedimentary deposits at the INL were done by Anderson (1991); Anderson and Bowers (1995); Anderson and Liszewski (1997); Geslin et al. (1997); Gianniny et al. (1997); Mark and Thackray (2002) (Fig. 5); and Bestland et al. (2002). Based on the previous work, sedimentary environments were split into three facies: lake, shoreline (interfluve/shoreline described by Mark and Thackray, 2002), and loess. The properties of facies used in this thesis are found in Figure 29, and are modified based on Fig. 5 (Mark and Thackray, 2002), and include example grain size distribution and cumulative frequency curves for lacustrine, shoreline, and loess facies.

Facies	Mean grain size	Clay content	Sorting	Skewness
Lake floor	Finer than 6.1 phi (fine silt) to finer than 7.8 phi (very fine silt); averages finer than 7.1 phi (very fine silt)	24%–60%	Poorly sorted*	Nearly symmetrical to strongly coarse skewed†
Playa bottom	4.6 phi (coarse silt) to finer than 7.3 phi (very fine silt); averages finer than 6.2 phi (fine silt)	18%–60%	Poorly sorted to very poorly sorted*	Strongly fine skewed to strongly coarse skewed†
Dune	2.7 phi (fine sand) to finer than 5.9 phi (medium silt); averages finer than 4.1 phi (coarse silt)	Usually 7%–19%	Poorly sorted to very poorly sorted	Typically strongly fine skewed to nearly symmetrical†
Loess	4.9 phi (coarse silt) to finer than 6.0 phi (medium silt); averages finer than 5.5 phi (medium silt)	15%–40%	Poorly sorted to very poorly sorted*	Typically strongly fine skewed to nearly symmetrical†
Channel	–2.4 phi (pebble) to 1.7 phi (medium sand); averages 0.2 phi (coarse sand)	less than 3% combined clay and silt	Ranges from moderately sorted to very poorly sorted	Strongly fine skewed to strongly coarse skewed
Interfluve	4.5 phi (coarse silt) to finer than 7.0 phi (fine silt); averages finer than 5.7 phi (medium silt)	9%–34%	Poorly sorted to very poorly sorted*	Strongly fine skewed to strongly coarse skewed†

Note: Data from Mark (1999). Sorting and skewness were calculated according to Folk and Ward (1957).

* These are maximum estimates of sorting due to a lack of grain-size data in the finer than ~8.2 phi range. The sediment may be more poorly sorted than indicated.

† These are maximum estimates of skewness due to a lack of grain-size data in the finer than ~8.2 phi range. The sediment may be less skewed than indicated.

Figure 5: Sediment characteristics and facies (table 1 of Mark and Thackray, 2002). In this thesis we use shoreline instead of interfluve.

Work done by Blair (2002), shown in Fig. 6, correlates sediment and basalt in three cores across the BLT. Blair (2002) notes that there are discontinuous sediment layers in the upper and lower portions of coreholes drilled across the BLT.

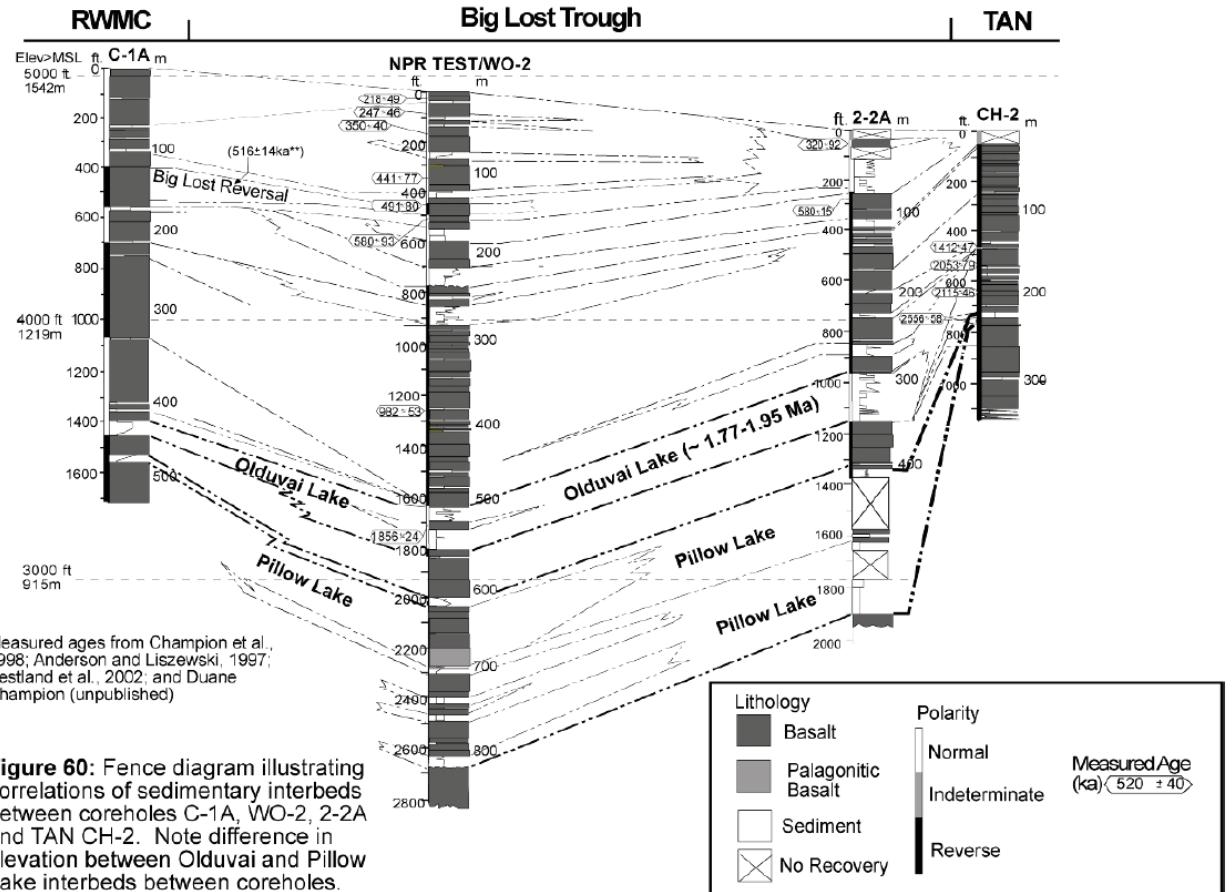

Figure 60: Fence diagram illustrating correlations of sedimentary interbeds between coreholes C-1A, WO-2, 2-2A and TAN CH-2. Note difference in elevation between Olduvai and Pillow Lake interbeds between coreholes.

Figure 6: Fence diagrams showing the stratigraphy within and on the edges of the Big Lost Trough (From Blair, 2001, Fig. 60). Figure 7 is a representation of sediment and basaltic units found at depth in four core holes drilled around the BLT (descriptions can be found in Blair, 2001), showing that there are deep persistent lakes (Olduvai Lake), older than 1.77 Ma. The correlated sediment between USGS 142 and NRF 15 may be representative of sediment found at a depth of 800 to 900 feet in corehole WO-2.

Chapter 3

3.1 Stratigraphic and Sedimentological Properties of Sediment intervals found in cores USGS 142 and NRF 15

The following section presents sedimentary properties and correlated intervals, separated into stratigraphic information, sorting, skewness, grain size, hydraulic conductivity, point counting, and detrital zircon information. The raw data can be found in the appendices.

Sediment was divided into separate intervals found in NRF 15 and USGS 142, with three intervals found in each USGS 142 (732-837 ft BLS) and NRF 15 (520-595 ft BLS). Intervals were divided into sediment found between basalt.

3.1.1 Stratigraphy

Using paleomagnetic inclination from Champion et al. (2013) along with unpublished paleomagnetic data from Duane Champion, USGS, written communication 2016, in conjunction with core logs for USGS 142 and NRF 15 a general stratigraphic column and correlated sediment (determined to be 884 ka to 988 ka) figure was created (Fig. 7). USGS 142 is 87.7% basalt and 12.2% sediment, with a bottom depth of roughly 836 feet below land surface (BLS) and a surface elevation of 5008 feet. Sediments that are found in USGS 142 are sand, silt, and clay and some combination of the three. NRF 15 is made up of 78.9% basalt and 21.1% sediment, with a bottom depth of 780 feet BLS, and has a surface elevation of 4842 feet. NRF 15 sediments are sand, silt, and clay or some combination of the three. Rhyolitic ash in USGS 142 was found at a depth of 115 feet. Sediment found outside of the correlation zone, seen in Fig. 9, was sparse and thin in both USGS 142 and NRF 15. NRF 15 has an abundance of non-recovery zones while USGS 142 has more complete sediment recovery.

In both core holes the basalt directly above the sediment of interest is related to the Matuyama Chron flow groups and is estimated to be 884 ka. The Bruhnes/Matuyama boundary (780 ka) is found at a depth of roughly 350 ft in NRF 15 and 500 ft in USGS 142. This depth

difference likely reflects variable subsidence, between the two core holes. Variable subsidence is also confirmed by the depth of the Jaramillo subchron flow found at the bottom of the two core holes.

The correlation of sediment intervals between NRF 15 and USGS 142 is determined in two ways. First is through paleomagnetic work done by Duane Champion, USGS (written communication 2016), which correlates basaltic flow groups through paleo-magnetic properties and assigns ages to identified flow groups. This shows that the thick sediment found near the bottom of each hole are between 884-988 ka (North late Matuyama to Jaramillo). Secondly correlative sediment intervals are very similar in their geometry, containing silt and clay that coarsens up into sand. This shows similar depositional environments in each core.

The core log description shown in the following section and general stratigraphy found in Fig. 7, identified 33 basaltic lava flows in USGS 142, erupted over a time period of roughly 988 ka. Detrital zircon samples (Fig. 7), represented as DZ1 and DZ2, were taken at a depth of 832 feet and 780 feet in USGS 142. Point counts, in 12 sections in USGS 142 and two sections in NRF 15, were taken for petrographic analysis and provenance interpretations. Grain size analysis samples were taken from several locations in NRF 15 and USGS 142, and were used for the calculation of skewness, sorting, hydraulic conductivity and ultimately facies identification of sediment intervals.

The age range of correlated sediment intervals, (Fig. 7) between USGS 142 and NRF 15 is thought to be 884 ka to 988 ka (North late Matuyama for NRF 15 and South late Matuyama for USGS 142 to Jaramillo) at depths ranging from 732 feet to 836 feet in USGS 142 and depths ranging from 527 to 595 feet in NRF 15. Flows from the South late Matuyama vent pinch out between USGS 142 and NRF 15. A complete interpretation of correlated basalt can be found in Fig. 2.

Areas of non-recovery are thought to be loose sediment that is blown into the formation when the drill bit passes through uncemented sediment intervals. The number on the right of each column (Fig. 7) is where sediment was taken for grain size analysis.

3.1.2

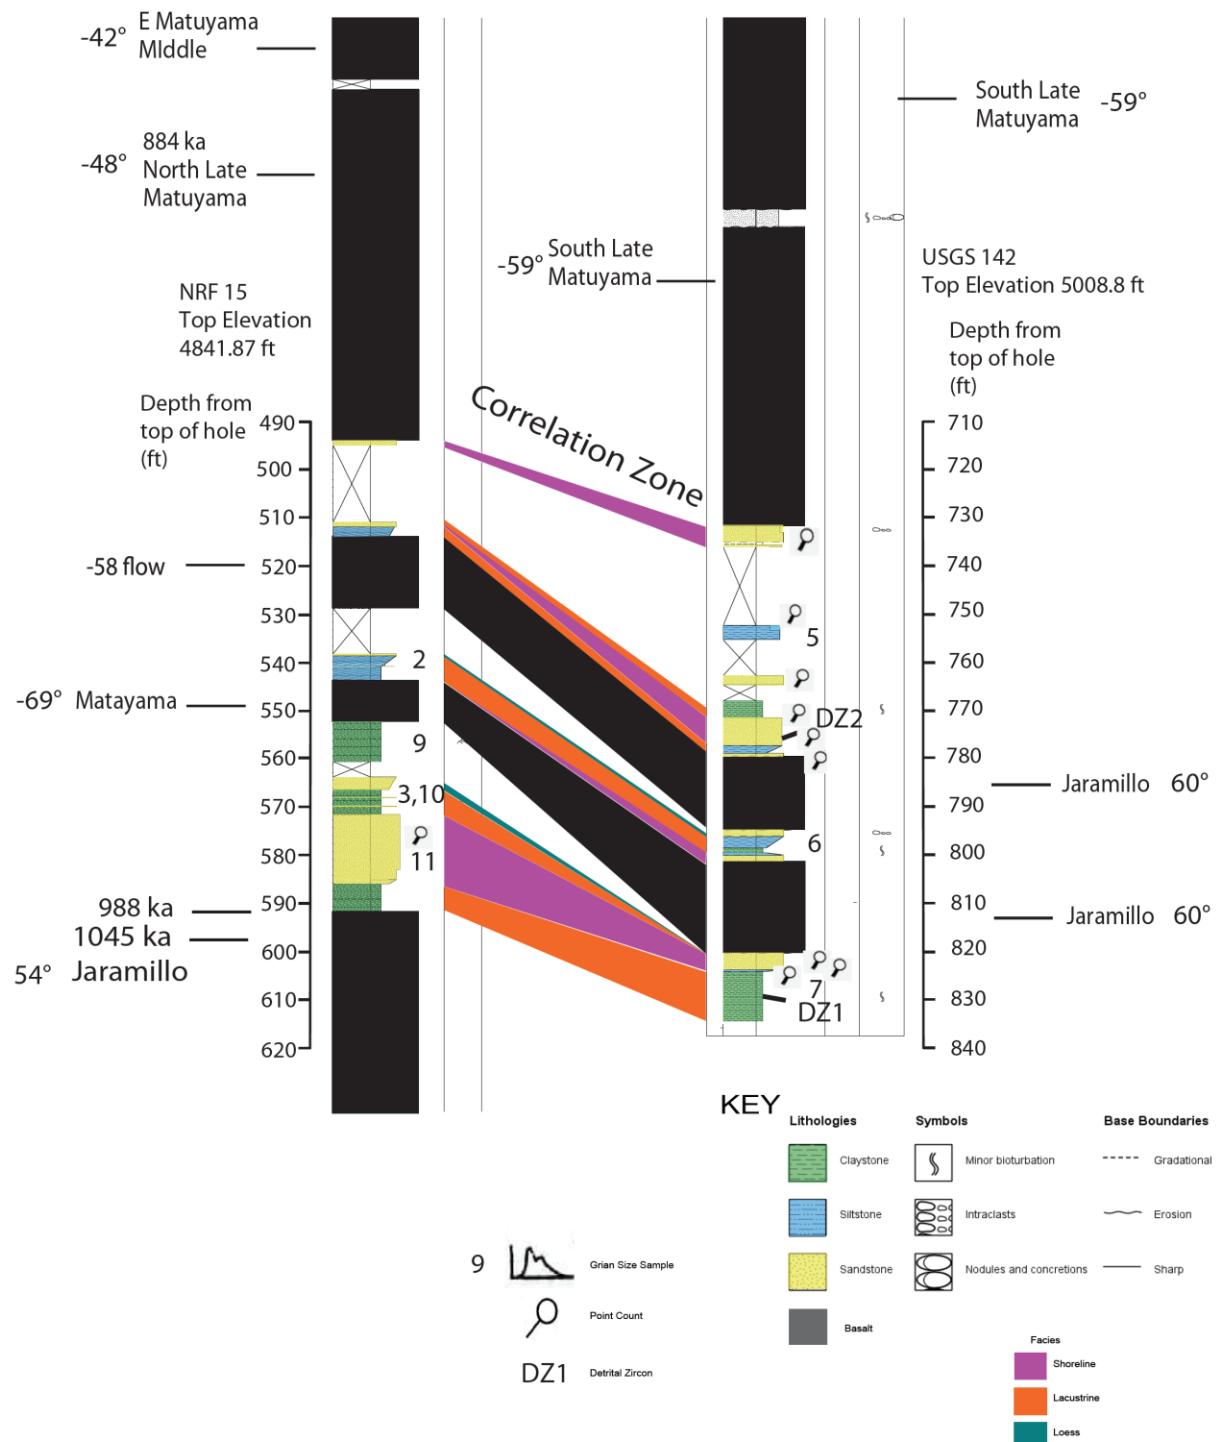

Figure 7: Correlation figure between USGS 142 and NRF 15, with inferred facies identification. I defined sediment intervals (numbers to the right of each column) based partially on intervals separated by basalt (degree number to the

side of each flow name is a different flow group) in USGS 142 and a separation of larger intervals for NRF 15. Intervals are as follows 5, 6, and 7 for USGS 142 and 2, 3, 9, 10, and 11 for NRF 15.

3.2 Sediment interbeds USGS 142

Sediment intervals are defined by units that are separated by basalt. The larger intervals are separated into smaller intervals, as follows: top, middle and bottom part of interval 5 in USGS 142 and interval 9, 10 and 11 in NRF 15. The data for all of the discussed properties of sediment (sorting, skewness, point counts, and hydraulic conductivity) can be found later in the report, and also in the appendix.

3.2.1 Interval USGS 142 7. Interval 7 is from 819.2-836.6 feet, Fig. 8. Although this is the bottom of the core used for this thesis, later drilling found several thick sedimentary units between about 846 ft and 1370 ft before bottoming out in a thick rhyolite deposit at 1396 ft BLS (USGS geophysical log accessed from the internet at http://ga2.er.usgs.gov/geologs/projects/inl/INL_Logarchive.htm). A sample for detrital zircon analysis was collected (sample DZI) at 832 feet BLS. Three point counts were taken at 823.5, 825.1 and 826.4 feet. Point counts were dominated by quartz and lithics (51% are felsitic volcanic lithics). There is bioturbation associated with rhizoliths at roughly 833.3 feet. In the cumulative frequency curve (Fig. 10) there are two distinct populations. There is a coarse sand population in the top of the interval. There is claystone in the middle and bottom of the interval. One coarse sandy lens was found in the middle of the fine grained section, USGS 142 7F. Smear slides show angular poorly sorted deposits in this section. Hydraulic conductivity ranged from 0.085 feet per day in sample USGS 142 7E to 10.6 feet per day in sample USGS 142 7B. Skewness values range from 0.674 for USGS 142 7A to 0.115 for 7E, 0.157 for 7G, and -0.068 for 7H to -0.093 for 7I.

USGS 142 interval 7

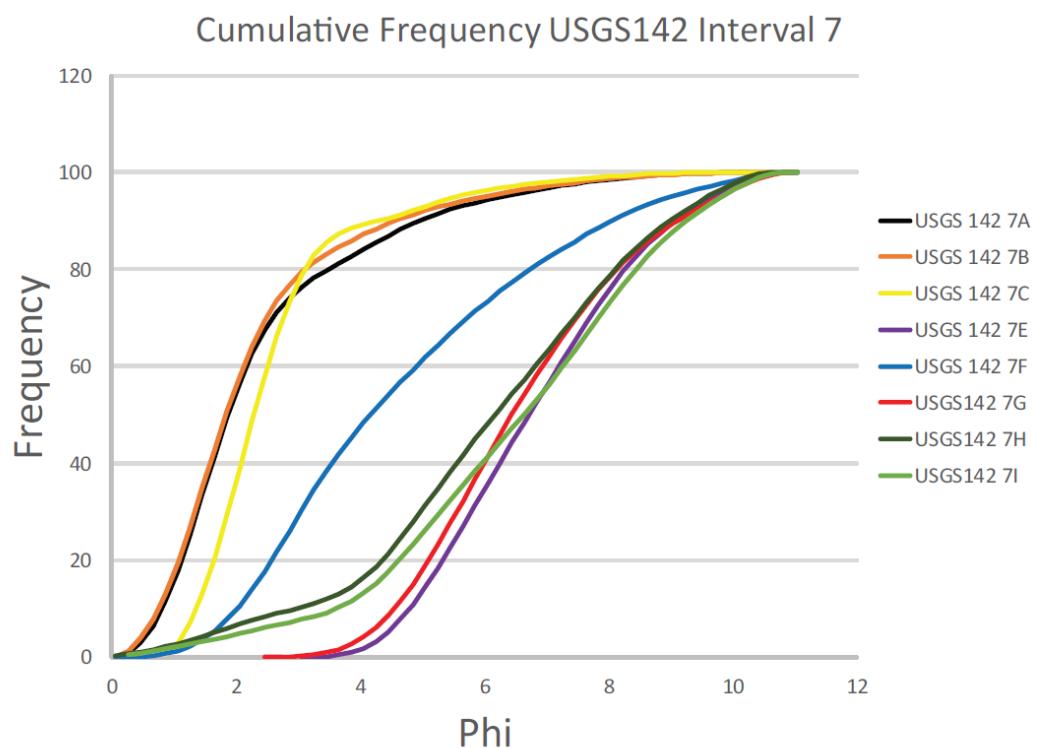

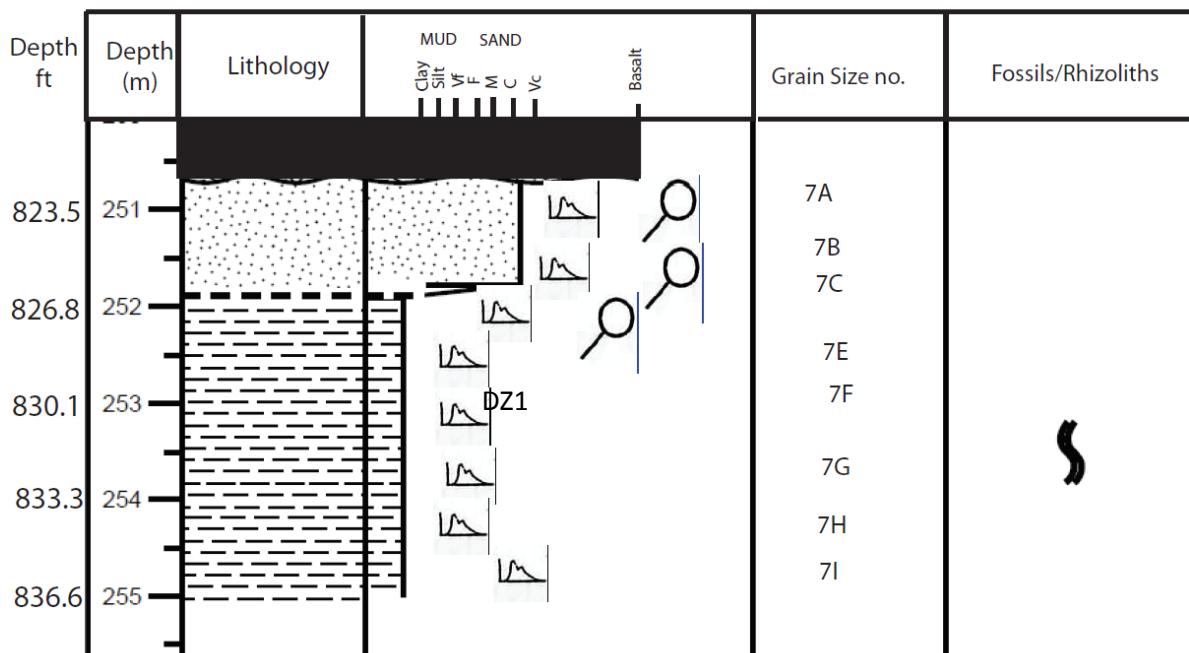

Figure 8: Stratigraphic and graphical representation of sediment USGS 142 interval 7. See figure 8 key for symbols.

3.2.2 Interval USGS 142 6. Interval 6 is from 796.3-803.1 feet. Five sediment samples were collected for grain size analyses (Fig. 9). Intraclasts were found at 797.2 feet and rhizoliths were noted at 800.5 feet. The cumulative frequency curve shows that there is little variation in grainsize between samples. The majority of sediment is in the fine sand to silt range. It grades from mostly fine sand and coarse silt to coarse sand. Smear slides show poorly sorted angular sediment deposits. Hydraulic conductivity ranges from 0.294 feet per day in USGS 142 6B to 1.97 feet per day in USGS 142 6E. Skewness values range from 0.261 for 6D to 0.436 for 6E.

USGS 142 interval 6

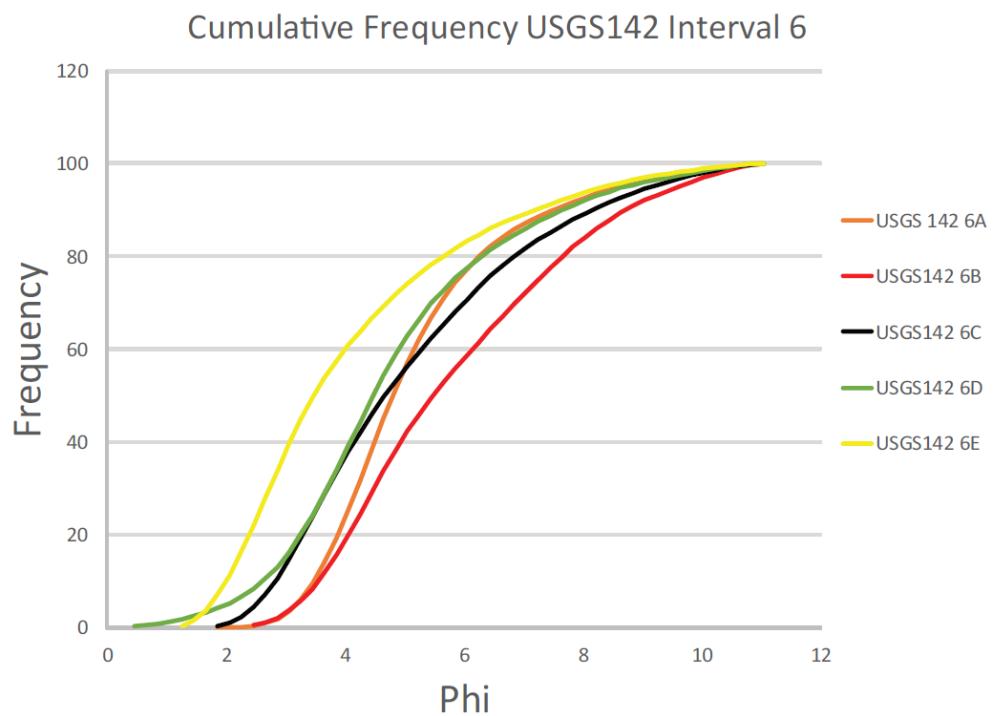

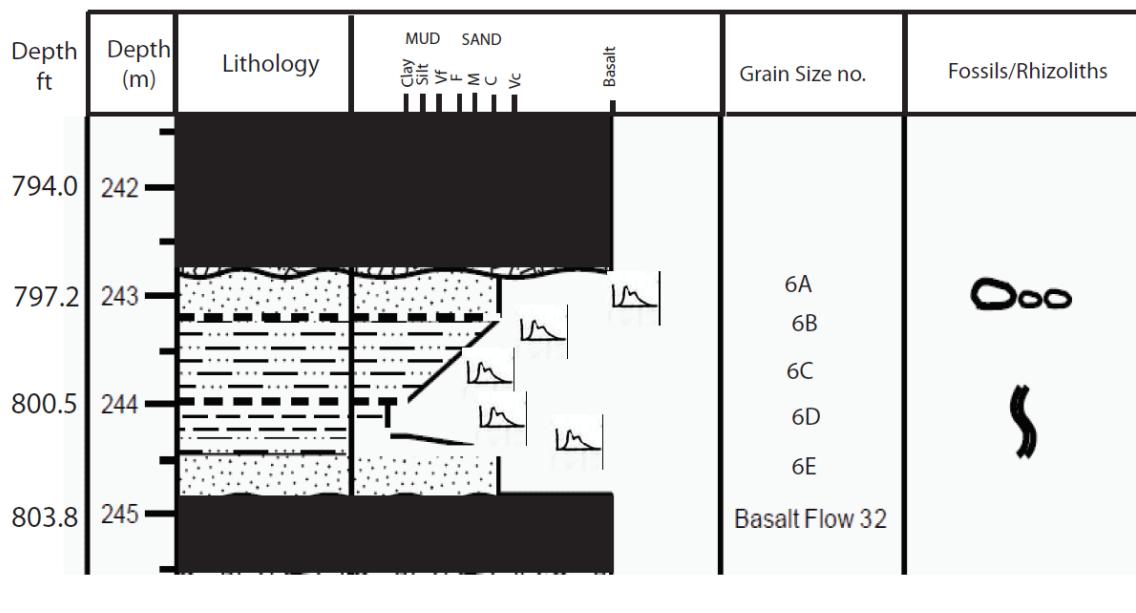

Figure 9: Stratigraphic and graphical representation of sediment USGS 142 interval 6. See figure 8 key for symbols.

3.2.3 Interval USGS 142 bottom of part 5. Interval bottom of 5 is from 774.3-780.8 feet.

Seven grain size samples were taken in the section, Fig. 10. USGS 142 5O is slightly bi-modal, while USGS 142 5S is mostly fine grained. The rest of the cumulative frequency curves here are similar and show coarse grained material. Detrital zircon analysis (sample DZ2) was collected at a depth of 780 feet. Two point counts were taken at 776.6 and 780.8 feet. Point counts are dominated by quartz and lithics, with 61% of lithics being volcanic (76% are felsitic). Smear slides show angular poorly sorted sediment. Hydraulic conductivity ranges from 0.863 feet per day in sample USGS 142 5S, to 5.18 feet per day in sample USGS 142 5P. Skewness values range from 0.098 for 5O to 0.522 for 5N.

USGS 142 interval bottom of 5

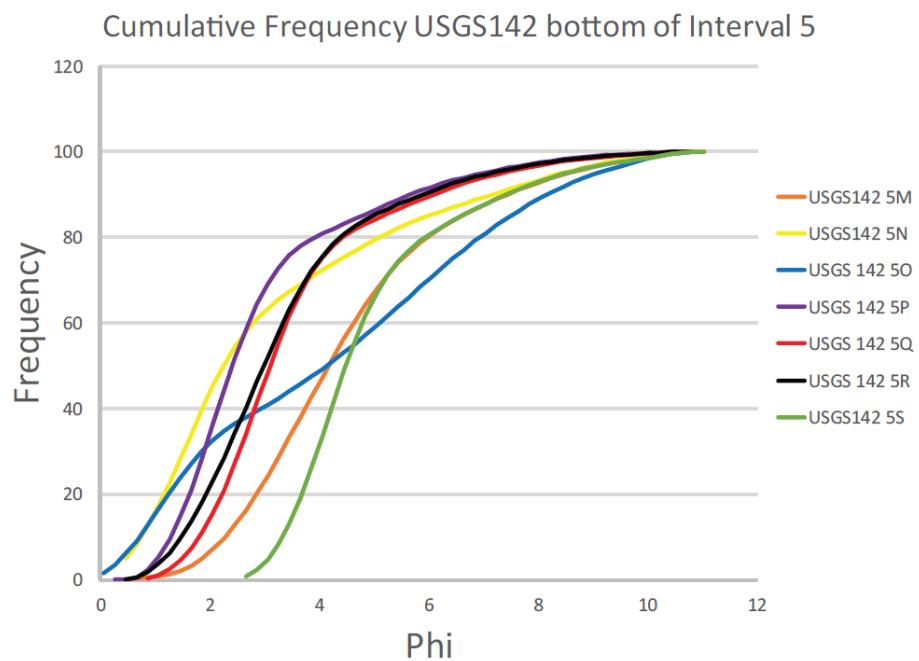

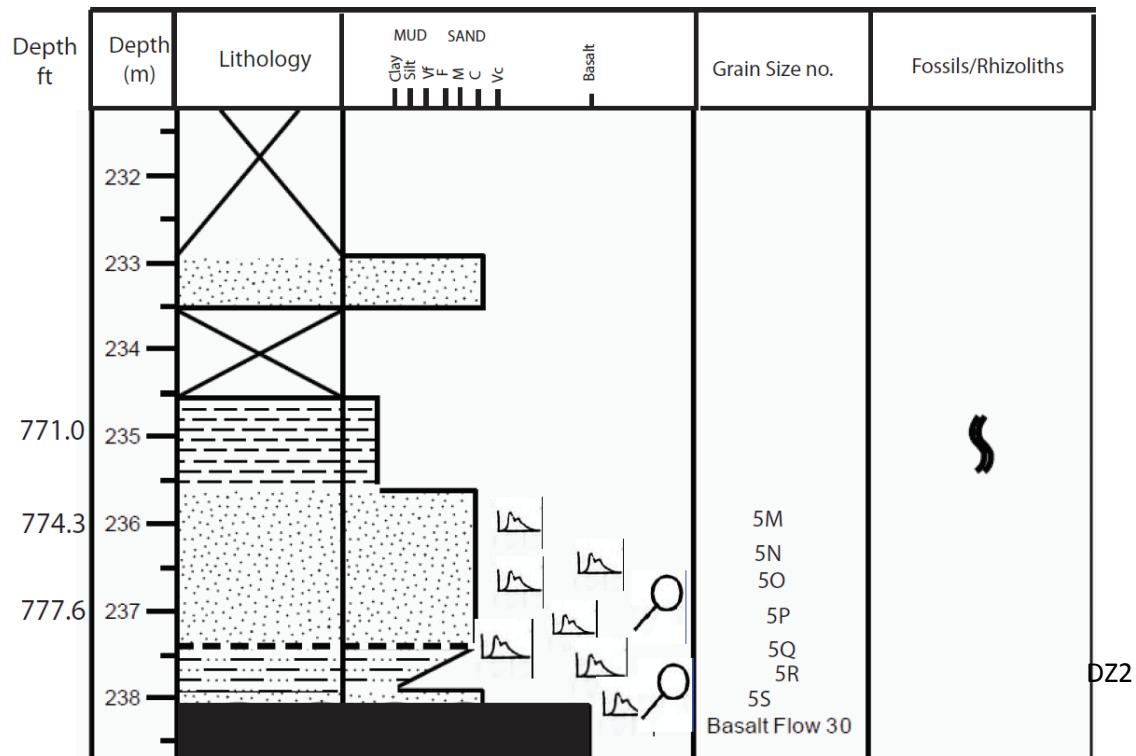

Figure 10: Stratigraphic and graphical representation of sediment USGS 142 interval bottom of 5. See figure 8 key for symbols.

3.2.4 Interval USGS 142 middle part of 5. Interval middle of 5 is from 764.4-774.3 feet in depth, Fig. 11. Thirty percent of this section was not recovered. Sediments are primarily coarse sand with a silty section at 769.4 feet. Point counts were taken in two sections, 764.4 feet and 769.4 feet. Point counts are dominated by quartz and lithics, with 62% volcanic lithics and (75% are felsitic). Bioturbation associated with rhizoliths was found at 771.7 feet. Cumulative frequency curves show general coarse sand with silt at USGS 142 5K. Smear slides show angular poorly sorted sediment. Hydraulic conductivity ranges from 0.464 feet per day in USGS 142 5K to 6.4 feet per day in USGS 142 5J. Skewness values range from 0.232 in 5K, to 0.403 in 5L.

USGS 142 interval middle of 5

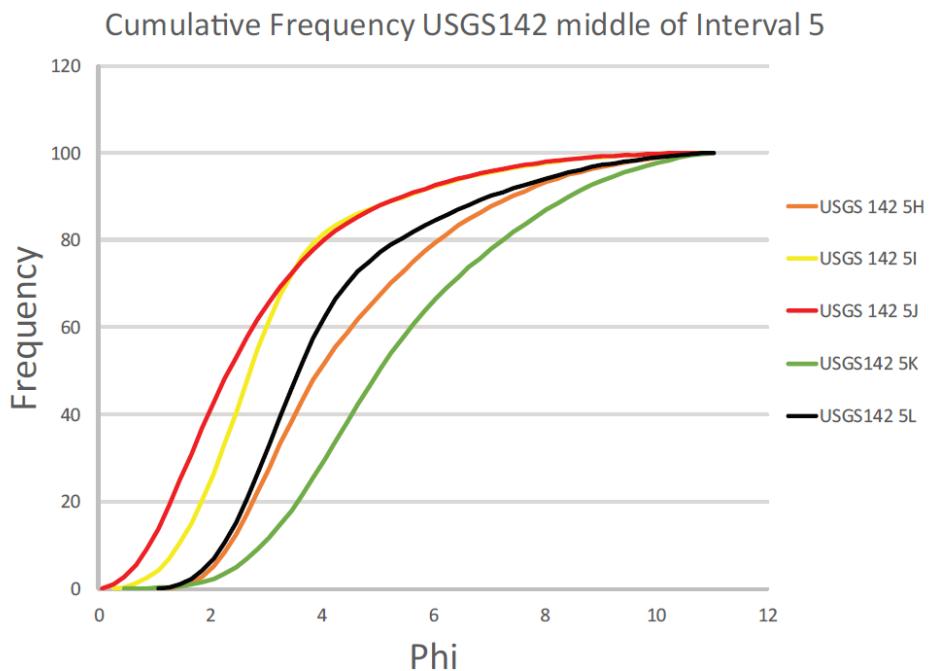

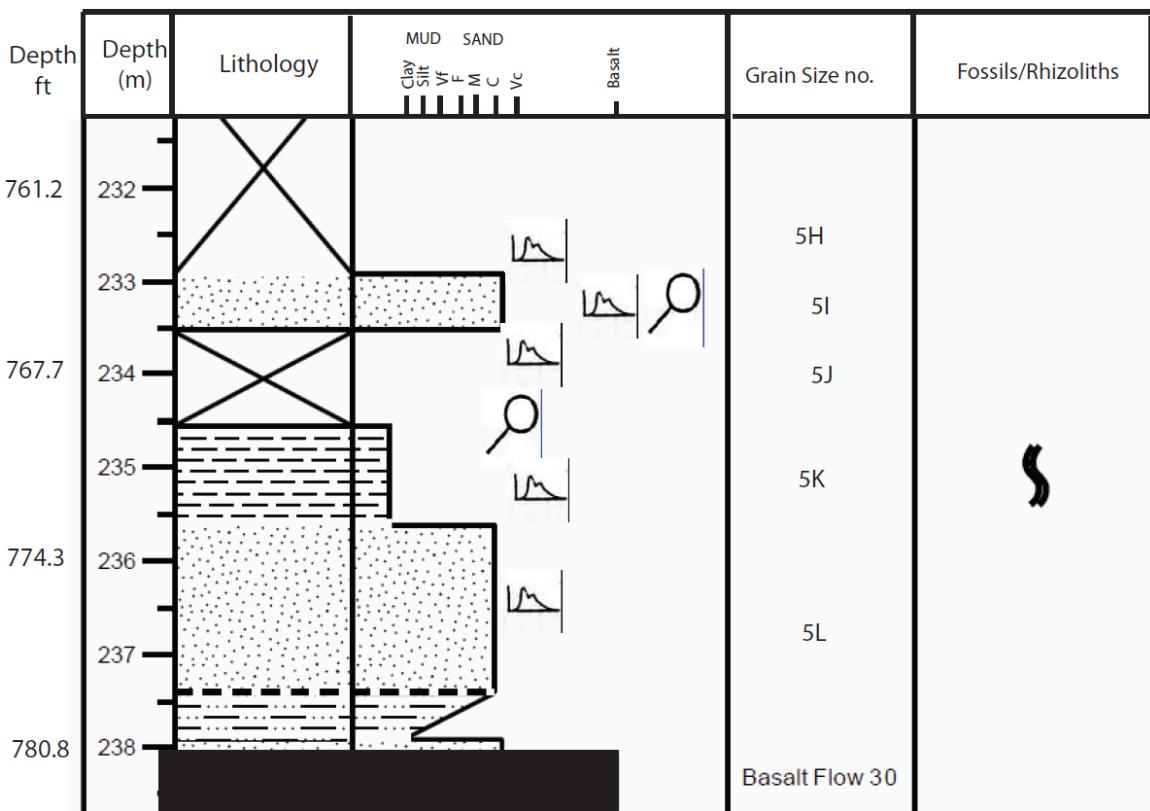

Figure 11: Stratigraphic and graphical representation of sediment USGS 142 interval middle of 5. See figure 8 key for symbols.

3.2.5 Interval USGS 142 top part of 5. Interval top of 5 is from 732.9-756.7 feet in depth. There is sand and silt in the top part of this section demonstrated by samples USGS 142 5D and 5E, Fig. 12. The section moves to silt and clay in samples USGS 142 5F and 5G (Fig. 12). There is a large area of non-recovery in the middle of this section, which accounts for 71.4% of the interval. Point counts were taken from the upper less consolidated coarser grained unit in 5D and 5E, and show a dominance of lithics and quartz. Of the total lithics in point counts, 70% are volcanic, and of that 73% are felsitic volcanic grains. Hydraulic conductivity, as estimated from grain size, ranged from 0.708 feet per day in sample USGS 142 5G to 4.05 feet per day in sample USGS 142 5E. Smear slides indicate angular poorly sorted sediment. Skewness values range from 0.000 in 5F to 0.396 in 5E.

USGS 142 interval top of 5

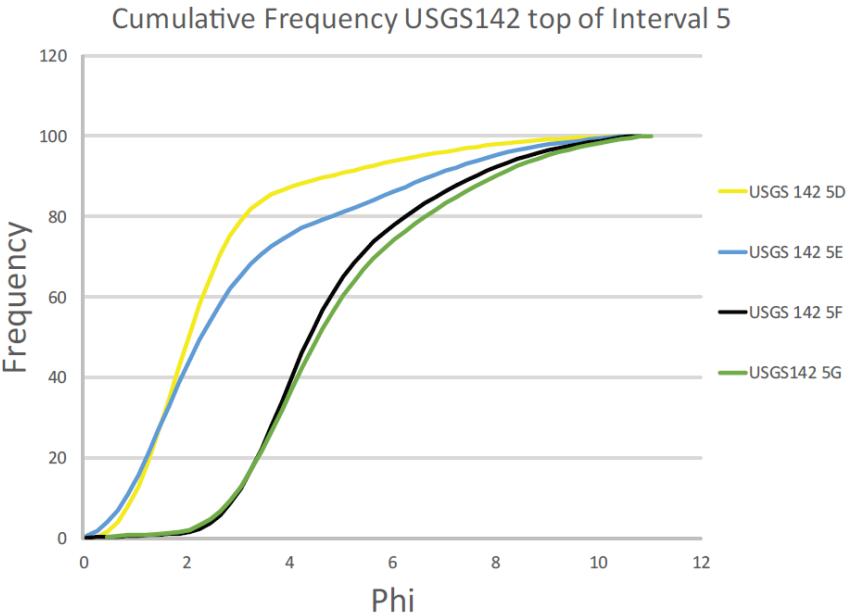

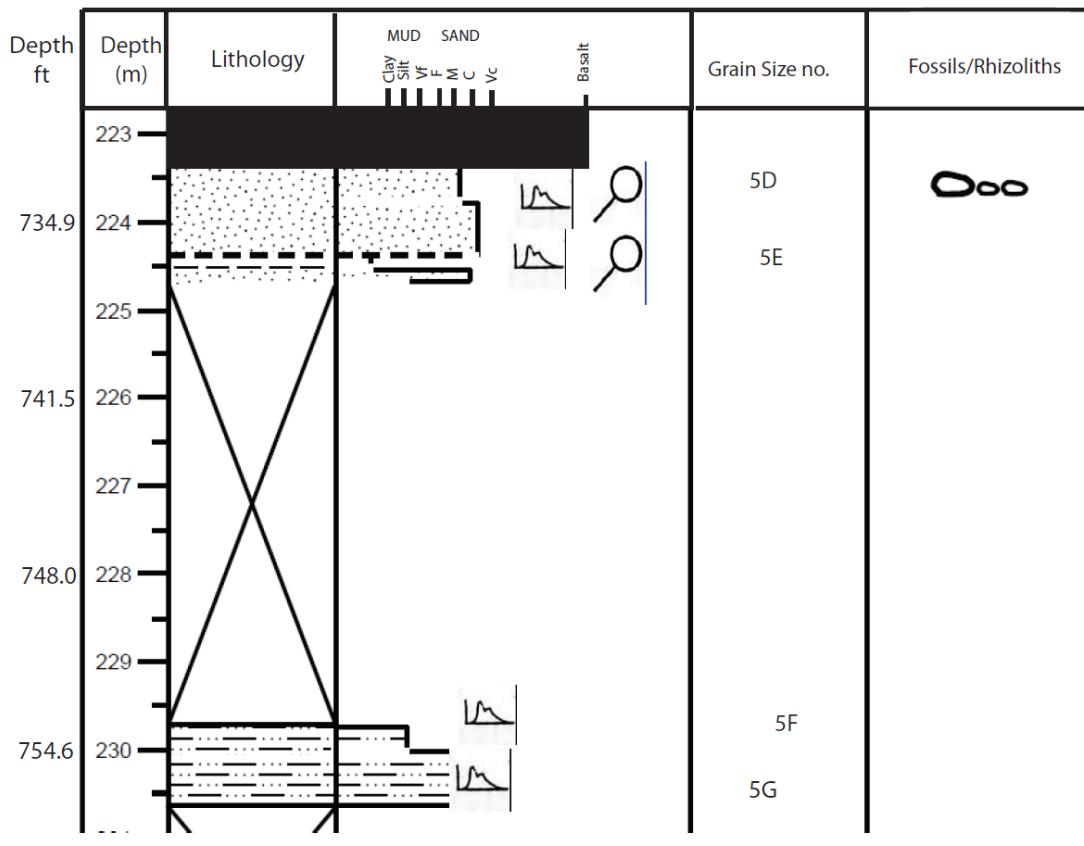

Figure 12: Stratigraphic and graphical representation of sediment USGS 142 interval top of 5. See figure 8 key for symbols.

3.3 Sediment interbeds NRF 15

3.3.1 Interval NRF 15 8. Interval 8 is found at a depth of 754.6 to 761.2 ft (Fig. 13). This is a massive clay to silt deposit with only one data point that confirms the fine grained nature of the unit. Smear slides show angular grains in poorly sorted sediment. Hydraulic conductivity is 0.0785 feet per day. Skewness is 0.014, or nearly symmetrical.

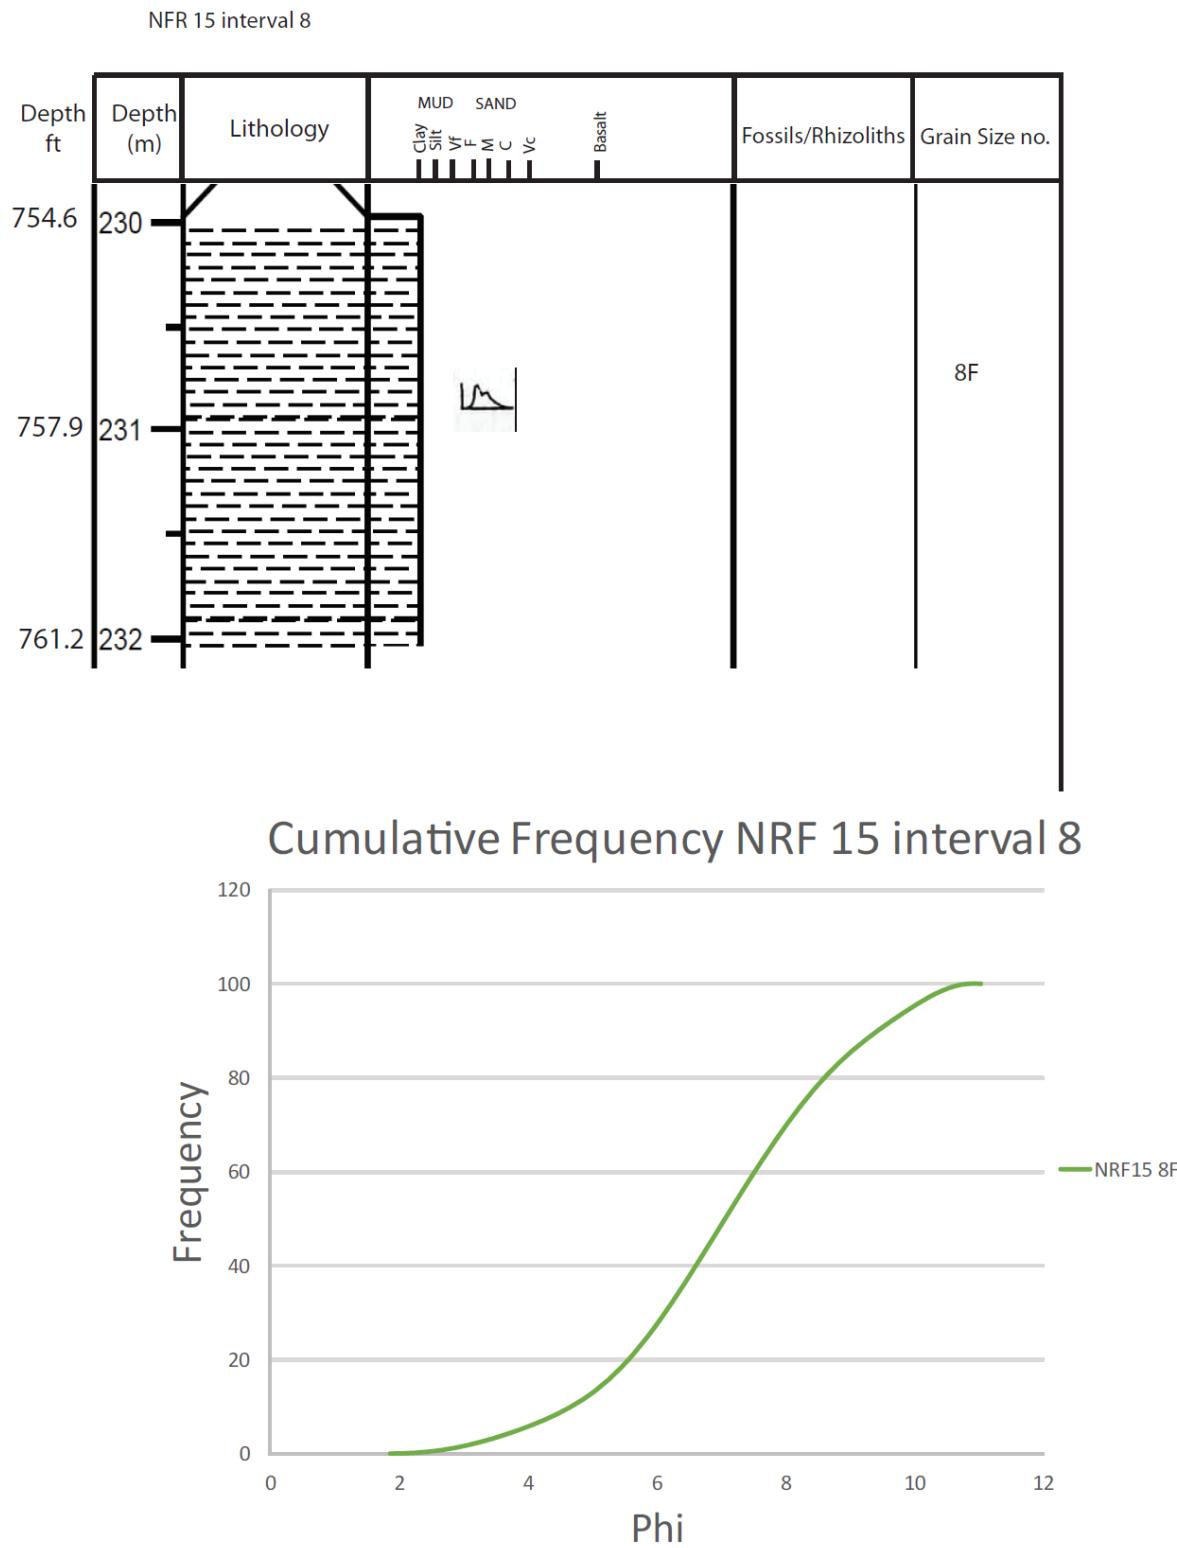

Figure 13: Stratigraphic and graphical representation of sediment NRF 15 interval 8. See figure 8 key for symbols.

3.3.2 Interval NRF 15 6. Interval is found at a depth of 739.8-745.7 ft, Fig. 14. Another massive silt and clay deposit with rhizoliths at 742.5 ft. The cumulative frequency curve shows NRF 15 6D and 6E are slightly coarser grained than samples NRF 15 6A, 6B and 6C. This coarser material shows up as lens in the massive unit. Smear slides show angular grains in poorly to very poorly sorted sediment. Hydraulic conductivity ranges from 0.095 feet per day in sample NRF 15 6D to 0.107 feet per day in sample NRF 15 6E. Skewness values range from 0.254 for NRF 15 6B to -0.308 for NRF 15 6D.

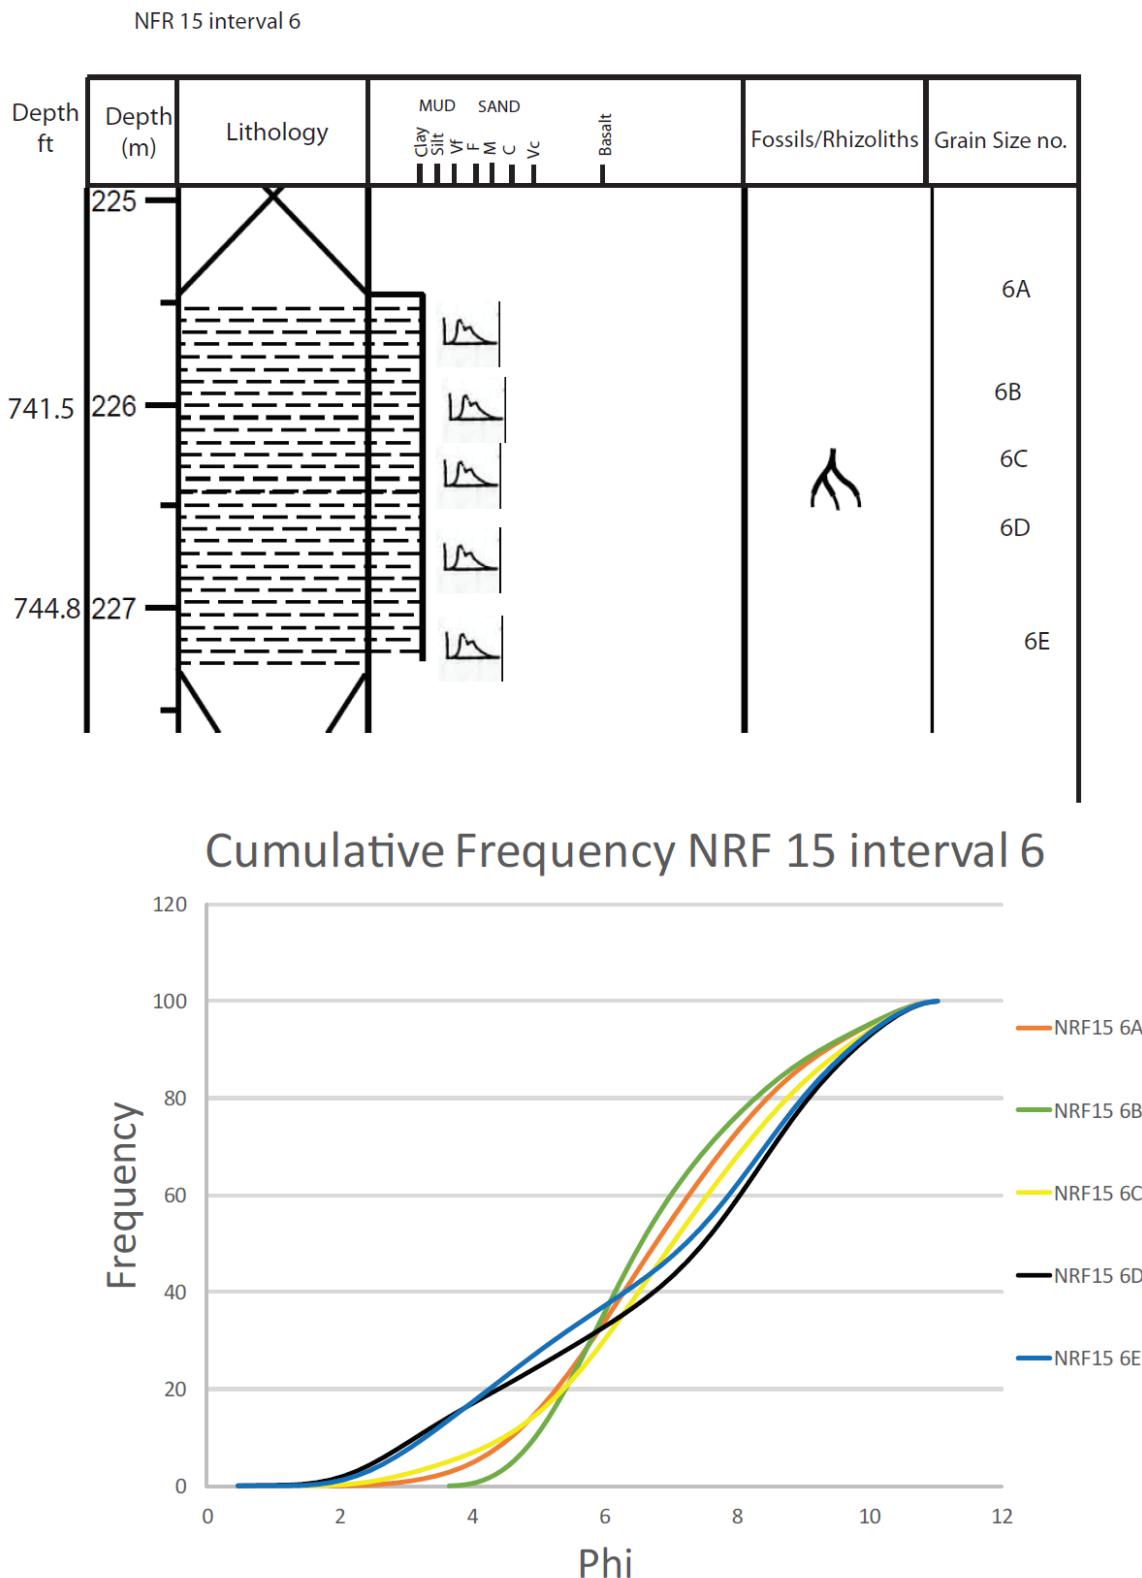

Figure 14: Stratigraphic and graphical representation of sediment NRF 15 interval 6. See figure 8 key for symbols.

3.3.3 Interval NRF 15 5. Interval is found at a depth of 732.6-739.8 ft (Fig. 15). This is a massive clay and silt unit. Rhizoliths show up at 734.3 ft. Cumulative frequency curves display same/similar grain sizes, silt to clay, throughout the interval. Smear slides show angular grains in poorly to very poorly sorted sediment. Hydraulic conductivity is fairly uniform ranging from 0.055 feet per day in sample NRF 15 5D to 0.0788 feet per day in sample NRF 15 5E. Skewness values range from 0.060 for NRF 15 5D, to 0.100 for NRF 15 5E.

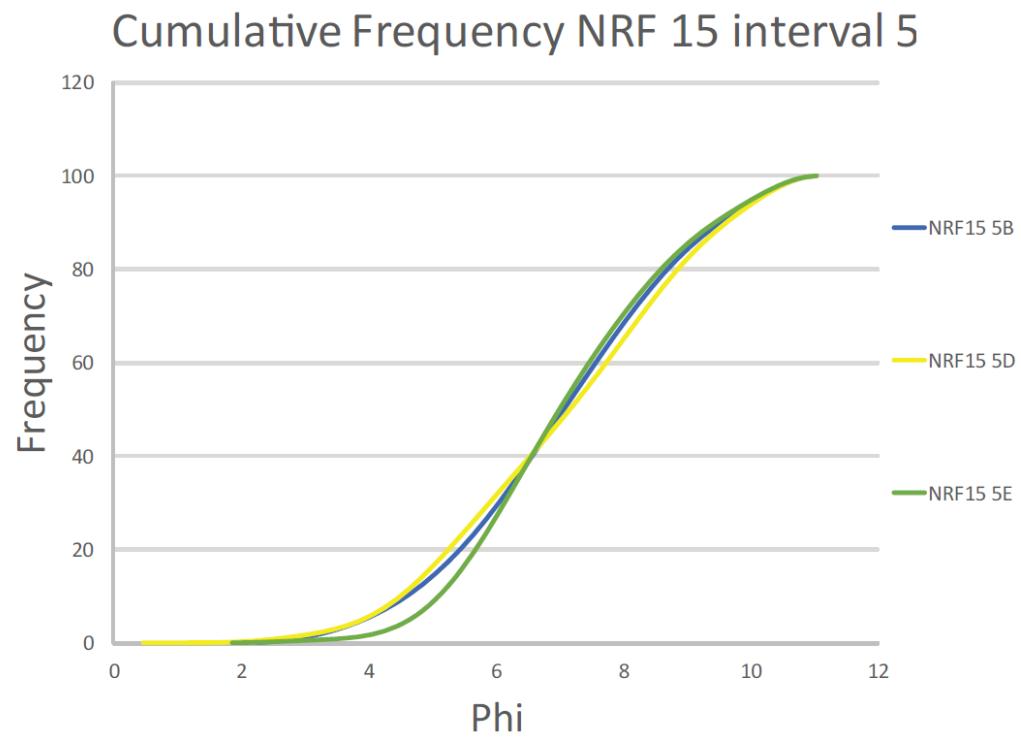

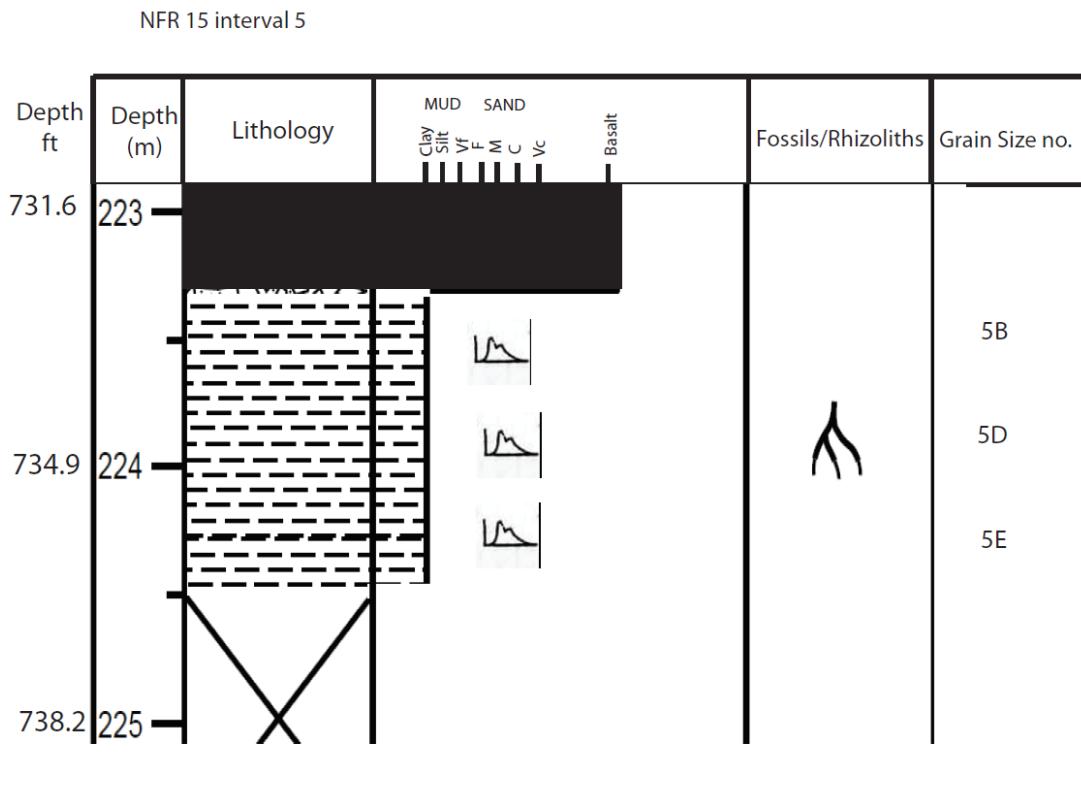

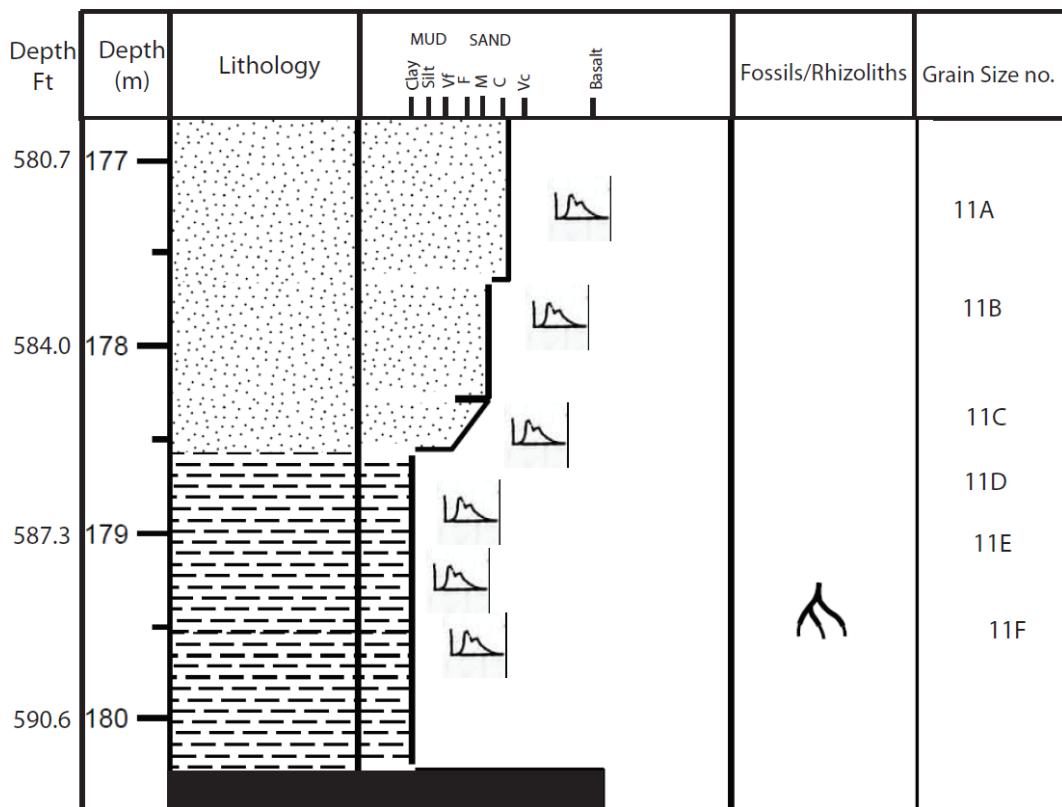

Figure 15: Stratigraphic and graphical representation of sediment NFR 15 interval 5. See figure 8 key for symbols.

3.3.4 Interval NRF 15 11. Interval 11 is found at a depth of 580.1-591.5 ft (Fig. 16). This represents a coarsening up interval that changes from fine silt and clay to medium sand. In the cumulative frequency curve NRF 15 11A is the coarsest sample, while NRF 15 11B and 11C are slightly finer grained. NRF 15 11D and 11E are fine grained silt and clay while NRF 15 11F is a sandy lens found in a fine grained unit. Rhizolith bioturbations show up at 588.9 ft. Point counts taken from loose sediment in NRF 15 11B were predominantly quartz and lithics, with 67% of lithics being volcanic (62% of those be felsitic). Smear slide show angular grains with poorly to very poorly sorted sediment. Hydraulic conductivity ranged from 0.058 feet per day in sample NRF 15 11E to 5.16 feet per day in sample NRF 15 11B. Skewness values range from 0.021 for NRF 15 11D to 0.622 for NRF 15 11C.

NFR 15 interval 11

Cumulative Frequency NRF 15 interval 11

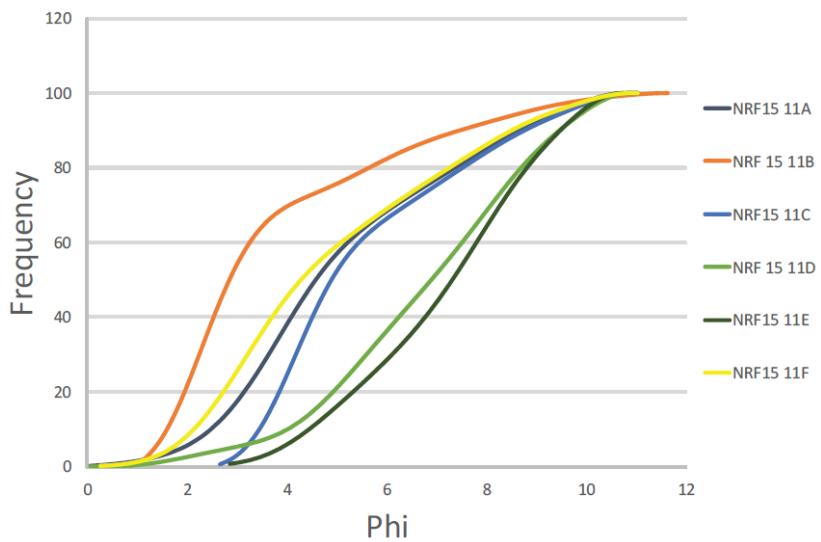

Figure 16: Stratigraphic and graphical representation of sediment NRF 15 interval 11. See figure 8 key for symbols.

3.3.5 Interval NRF 15 10. Interval 10 is found at a depth of 563.6-571.5 ft (Fig. 17). The base of this unit is silt and clay with fine grained sandy lenses at regular intervals. The section is topped with a coarsening up sandy unit. Rhizoliths are found at both 568.9 and 569.9 ft. The cumulative frequency curves are very similar except for NRF 15 10E which has a coarse grained distribution. NRF 15 10E is a lens of coarse grained material in a silt and clay unit. Other lenses were found while creating the stratigraphic column but only NRF 15 10E was a direct sample of a coarse grained lens. Smear slides show angular grains that are poorly to very poorly sorted. Hydraulic conductivity ranges from 0.039 feet per day in sample NRF 15 10C to 0.140 feet per day in sample NRF 15 10E. Skewness values range from -0.072 for NRF 15 10A, to -0.379 for NRF 15 10E.

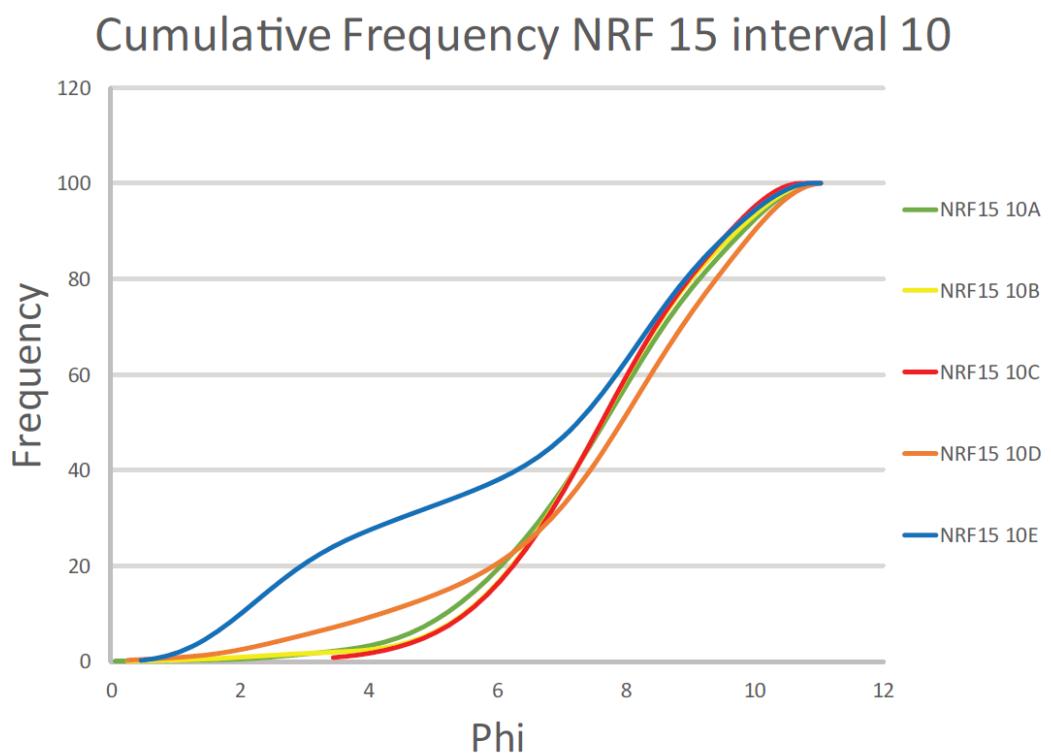

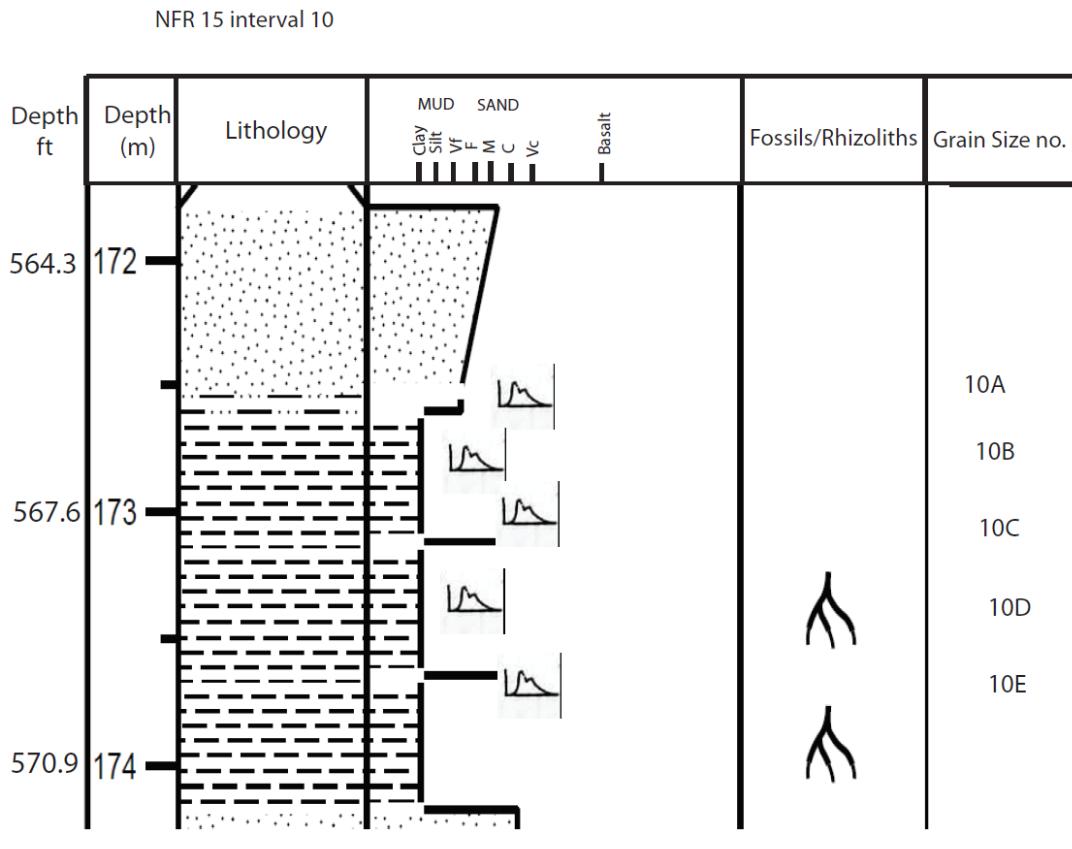

Figure 17: Stratigraphic and graphical representation of sediment NRF 15 interval 10. See figure 8 key for symbols.

3.3.6 Interval NRF 15 9. Interval 9 is found at a depth of 552.2-560.0 ft, Fig. 18. It is massive silt and clay. A single fine sand grained sample was collected from the very top of the interval in sample NRF-15 9A. Rhizoliths are found at 556.1 ft. Smear slides show angular grains that are poorly to very poorly sorted. Hydraulic conductivity ranges from 0.051 feet per day for sample NRF 15 9F to 0.568 feet per day in sample NRF 15 9A. Skewness values ranged from 0.068 for NRF 15 9B, to 0.327 for NRF 15 9A.

NRF 15 Interval 9

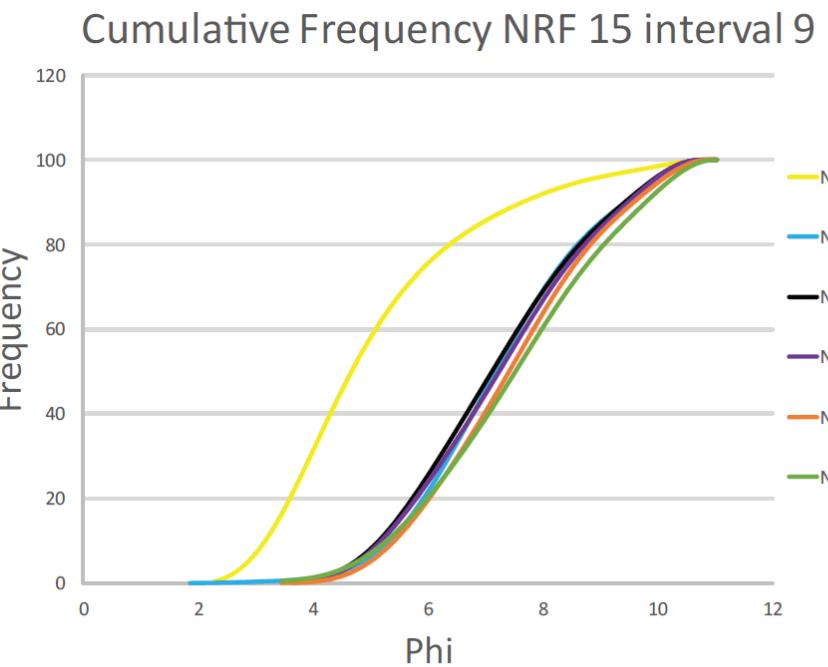

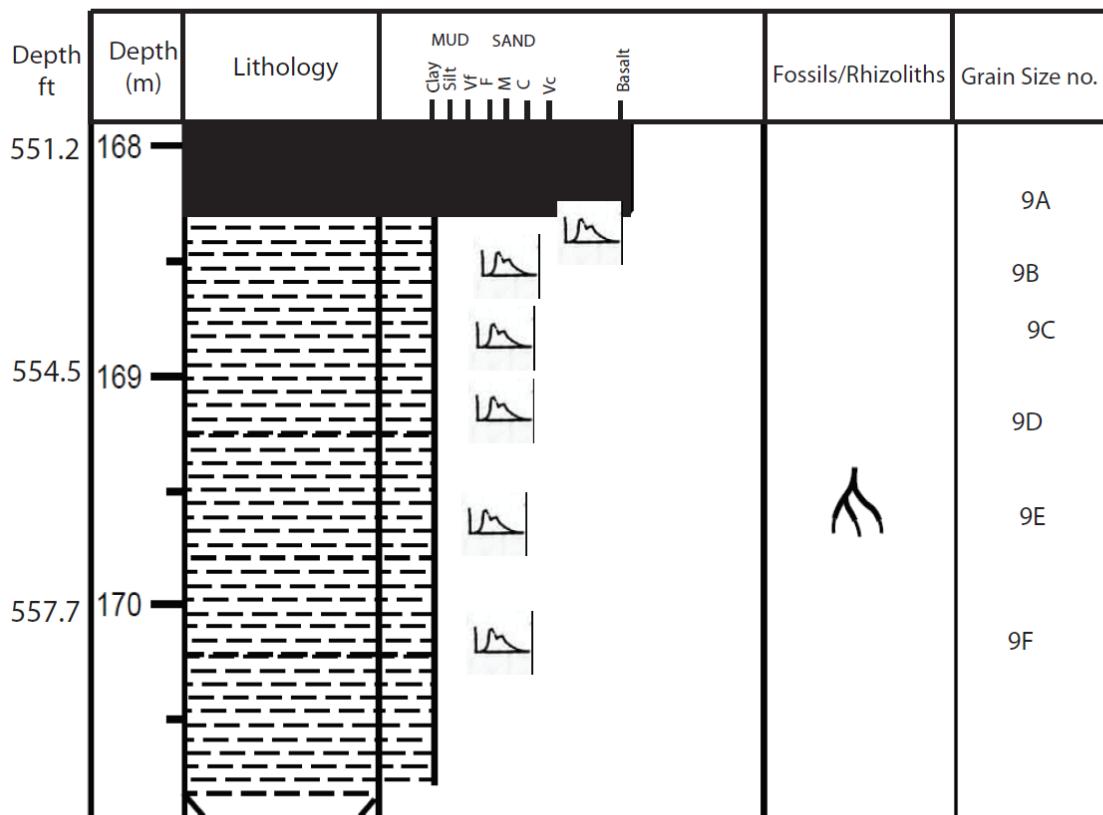

Figure 18: Stratigraphic and graphical representation of sediment NLF 15 interval 9. See figure 8 key for symbols.

3.3.7 Interval NRF 15 2. Interval 2 is found at depths from 538.1-543.6 ft, Fig. 19. The cumulative frequency curves show bi-modal grain size distribution toward the top of the section. This is a coarsening up interval, with fine grained silt and clay at the bottom and coarser material at the top of the interval. Rhizoliths show up at a depth of 542.3 ft. Smear slides show angular grains that are poorly to very poorly sorted. Hydraulic conductivity range from 0.099 feet per day in sample NRF 15 2C to 0.173 feet per day in sample NRF 15 2B. Skewness values ranged from -0.397 for NRF 15 2D to 0.149 for NRF 15 2F.

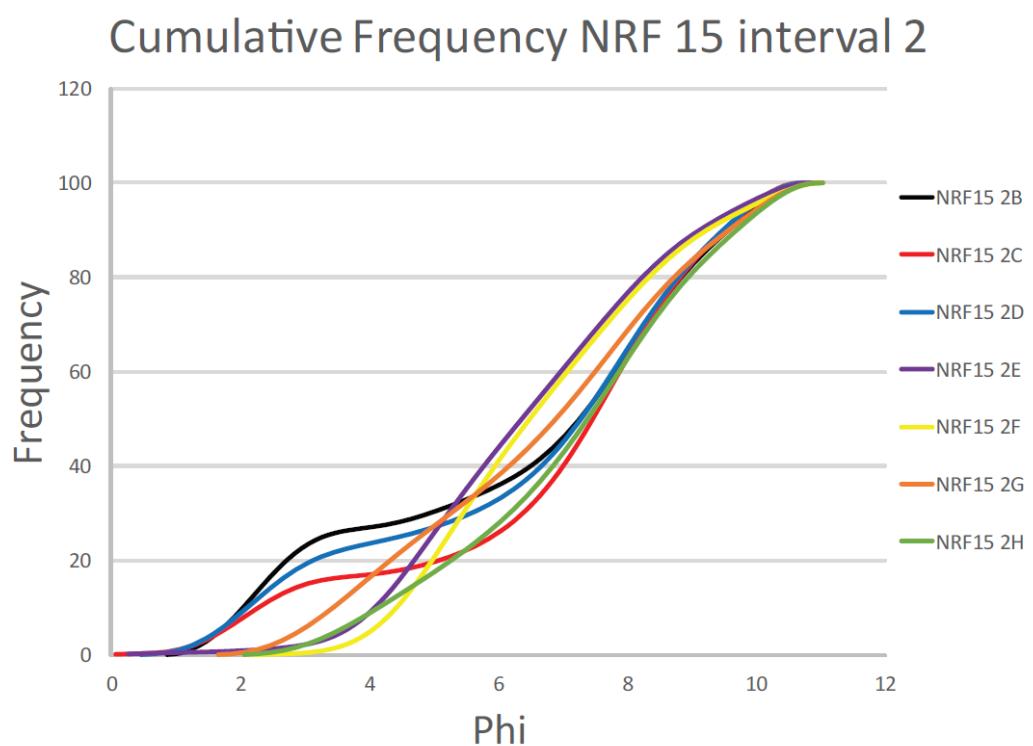

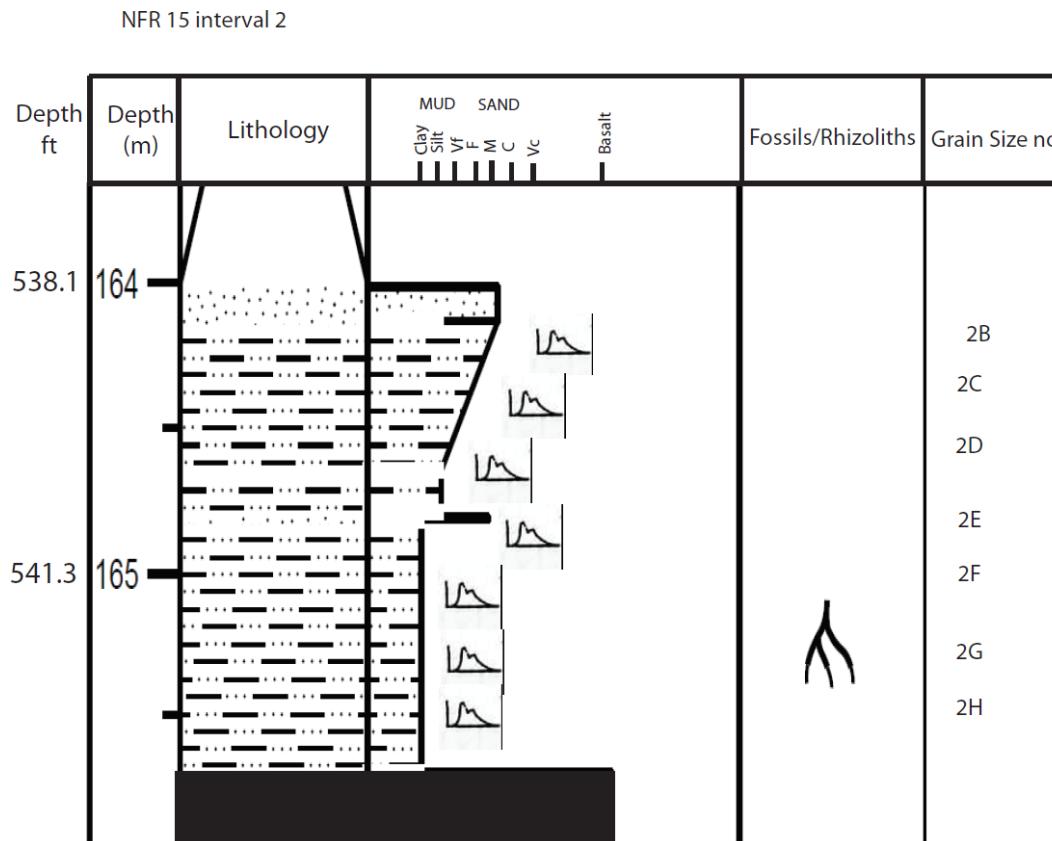

Figure 19: Stratigraphic and graphical representation of sediment NRF 15 interval 2. See figure 8 key for symbols.

3.4 Sedimentary intervals correlated between USGS 142 and NRF 15

3.4.1 The sediment intervals at 511-514 feet BLS in NRF 15 (unnamed) and at 773-781

BLS in USGS 142 (interval 5), Fig. 20, are seen as similar geometry of sediment between cores. This geometry is interpreted as a coarsening up or shallowing up sequence, which is bounded by basalt on the top and the bottom. The correlated unit between NRF 15 unknown and USGS 142 bottom of interval 5 is fine grained silt and sand that coarsens into fine to medium sand. The upper portions of USGS 142 interval 5 is extensive and thick showing two other units, within interval 5, that grade from silt and clay into fine to medium sand. This upper portion of USGS 142 5 has fine grained silt and clay and fine sand, but could not be correlated to the upper portion of NRF 15 unnamed.

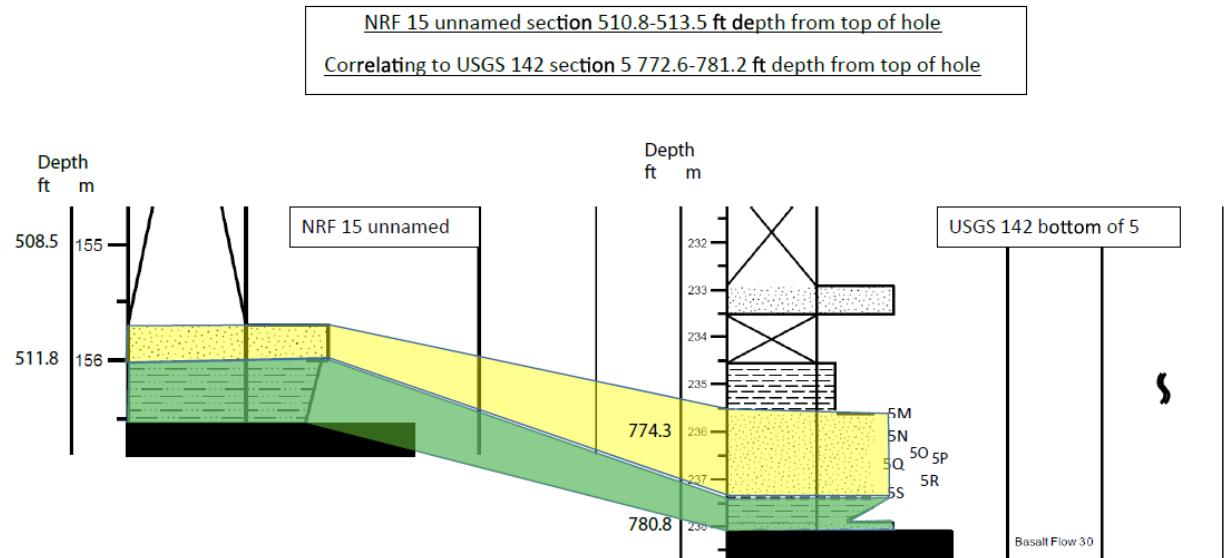

Figure 20: NRF 15 unnamed correlated with USGS 142 bottom of 5. See figure 8 key for symbols.

3.4.2 The sediment interval at 538-543 feet BLS in NRF 15 (interval 2) and at 797-800 feet BLS in USGS 142 (interval 6), (Fig. 21) correlate based on each interval having a similar coarsening up grainsize bounded by basalt on the top and the bottom. The correlative unit between NRF 15 interval 2 and USGS interval 6 shows silt and clay sediment that coarsens up to sand and a bi-modal distribution. This bi-modal unit is the only interval that is found in both USGS 142 and NRF 15 that fits the definition a bi-modal grain size distribution. Bioturbation and rhizoliths help to confirm a shallow lake facies in both intervals. In the bottom USGS 142 interval 6, there is a thick lens of fine to medium sand that could be associated with loess deposition.

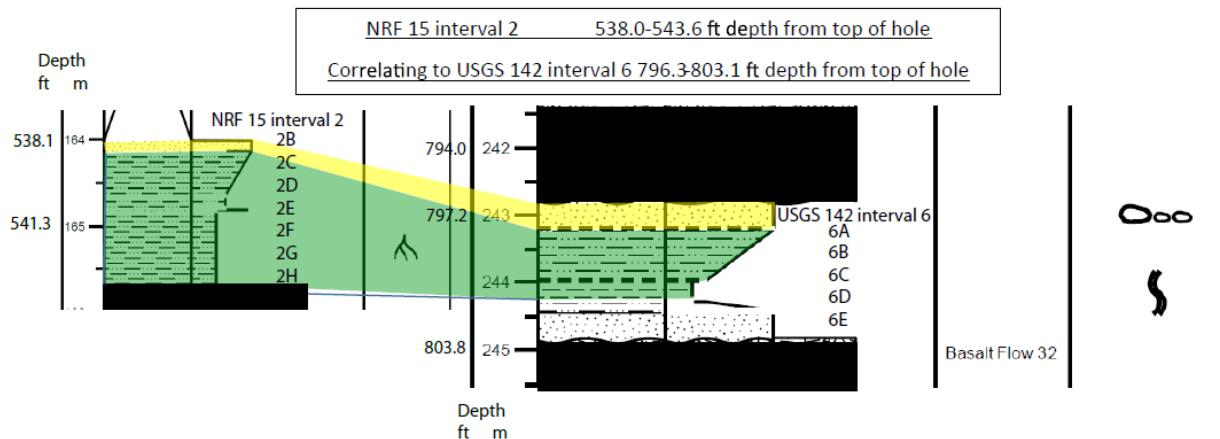

Figure 21: NRF 15 interval 2 correlated with USGS 142 interval 6. See figure 8 key for symbols.

The cumulative frequency curve for these correlated intervals is seen in Fig. 22. This graph shows us that NRF 15 sediment in interval 2 (dashed line) is dominated by bi-modal sediment and silt to clay. USGS 142 interval 6 on the other hand contains coarse sand. This represents a deepening of lake facies toward NRF 15.

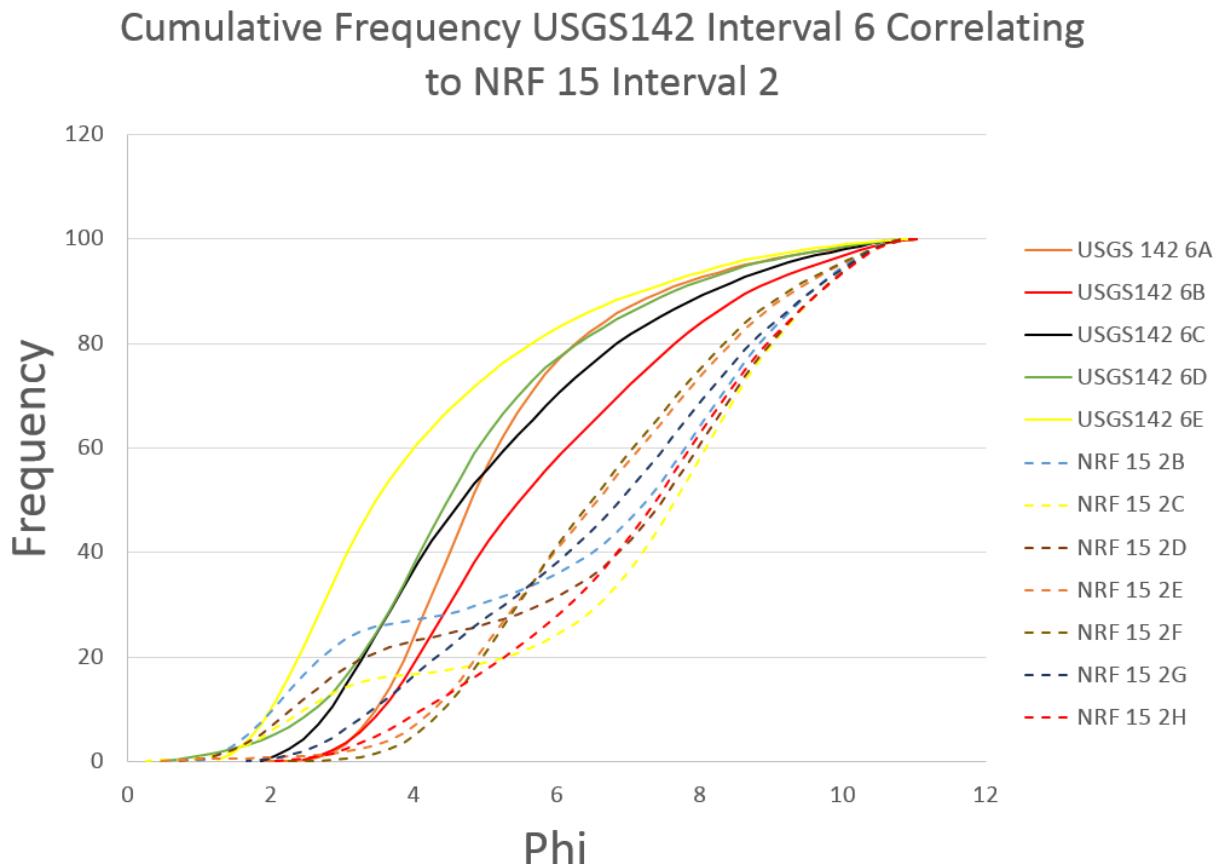

Figure 22: Cumulative Frequency curves for USGS 142 (solid lines) interval 6 and NRF 15 (dashed line) interval 2 Correlation between USGS 142 and NRF 15.

3.4.3 The sediment interval at 580-591 feet BLS in NRF 15 (interval 11) and at 823-836 feet BLS in USGS 142 (interval 7), fig 23, is a coarsening up sequence that is bounded by basalt on the top and the bottom. Correlation of NRF 15 interval 11 and USGS 142 interval 7 shows two massive clay and silt units that grade into fine to medium sand. Rhizoliths and bioturbation are found within the clay portions of both cores indicating a shallow lake. These are the thickest continuous deposits found in all the sedimentary intervals between both NRF 15 and USGS 142.

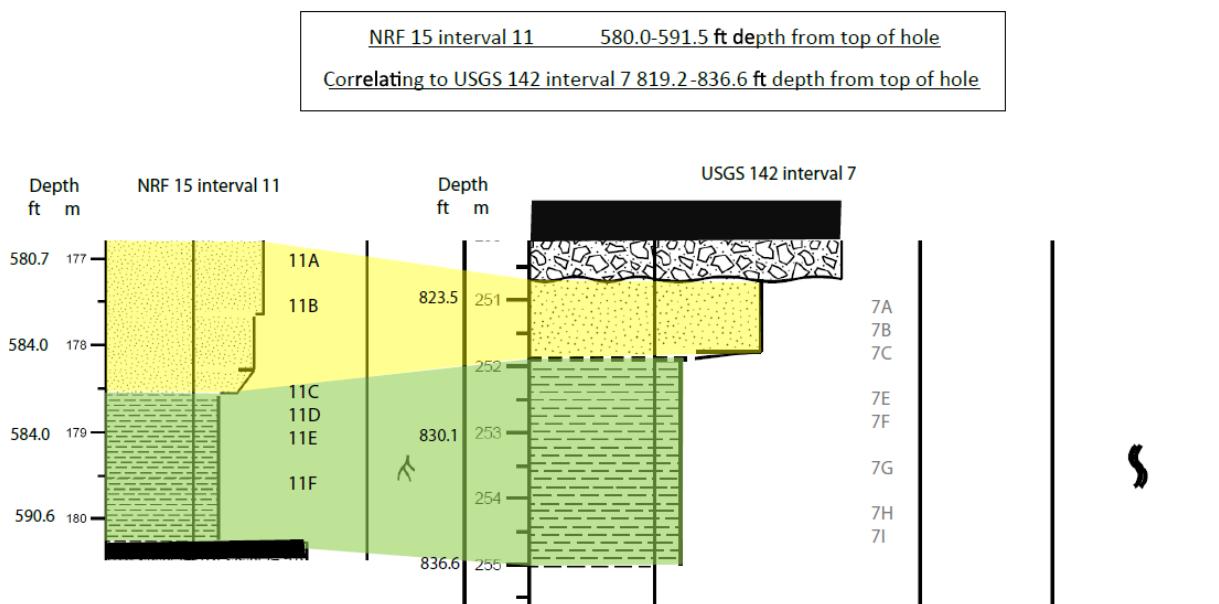

Figure 23: NRF 15 interval 11 correlated with USGS 142 interval 7. See figure 8 key for symbols.

The cumulative frequency curve comparing these intervals is found in Fig. 24. There are very similar grain size frequency curves between the two cores with silt and clay that coarsens up into sand. Also there are sandy lenses within the fine grained clay and silt found in each interval. This is interpreted to represent similar depositional environments between cores.

Cumulative Frequency USGS142 Interval 7 Correlating to NRF 15 interval 11

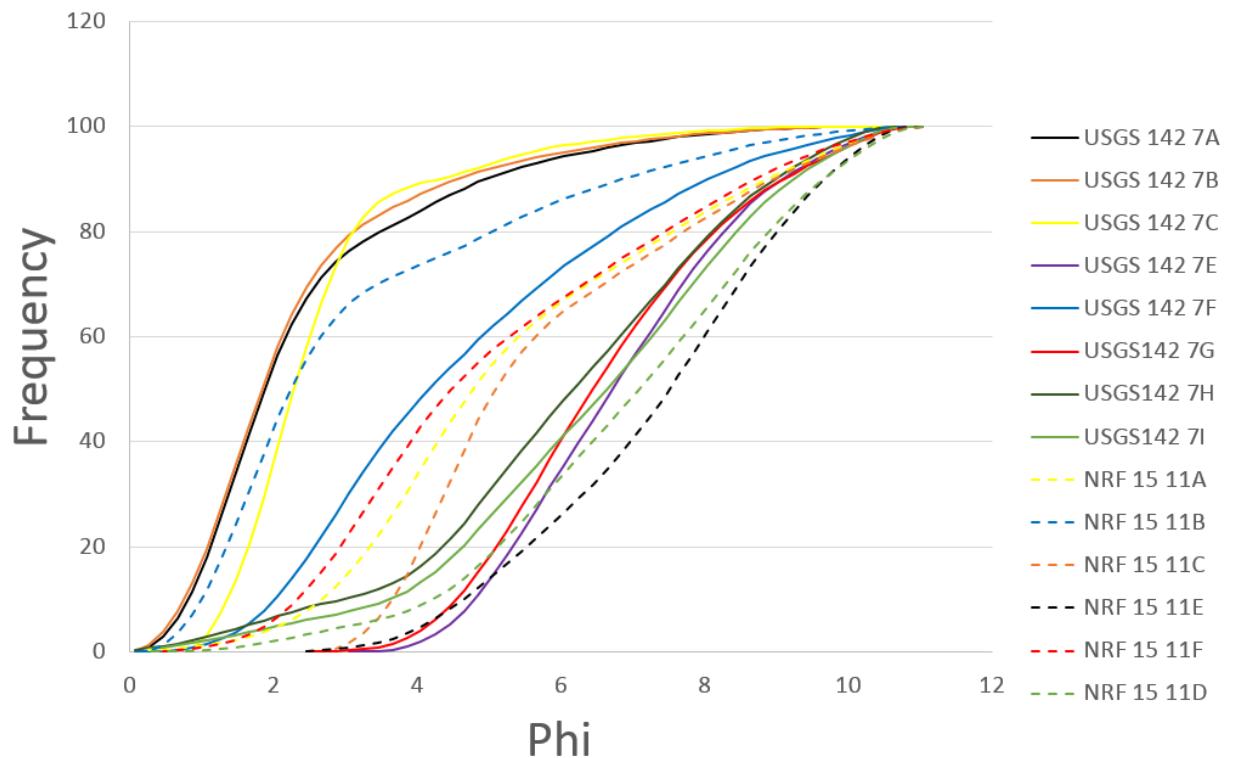

Figure 24: Cumulative frequency curves comparing USGS 142 interval 7 (solid lines) which is correlated to NRF 15 (dashed lines) interval 11. The two correlated intervals and representative curves match up well.

3.5 Synthesis

Sediment characteristics: Sorting and Skewness

3.5.1 Sorting

$$\text{Equation used (Tucker, 2001)} \sigma\Phi = \frac{(\Phi_{84} - \Phi_{16})}{4} + \frac{(\Phi_{95} - \Phi_5)}{6.6}$$

Figure 25 shows sorting compared with mean grain size for all samples analyzed from USGS 142 and NRF 15. All values are in the poorly sorted to very poorly sorted range as indicated by values greater than 1.00 on the horizontal axis. The graphical representation shows no real correlation for sorting values, though it should be noted that coarser grained samples are generally better sorted. Better sorted coarse grained samples are represented by values between 1 and 2.5 on the horizontal axis and coarse grained sediment seen as values between 2 and 3.5 phi on the vertical axis. Good sorting is representative of winnowing and reworking of shoreline and loess deposits (fine and medium sand samples).

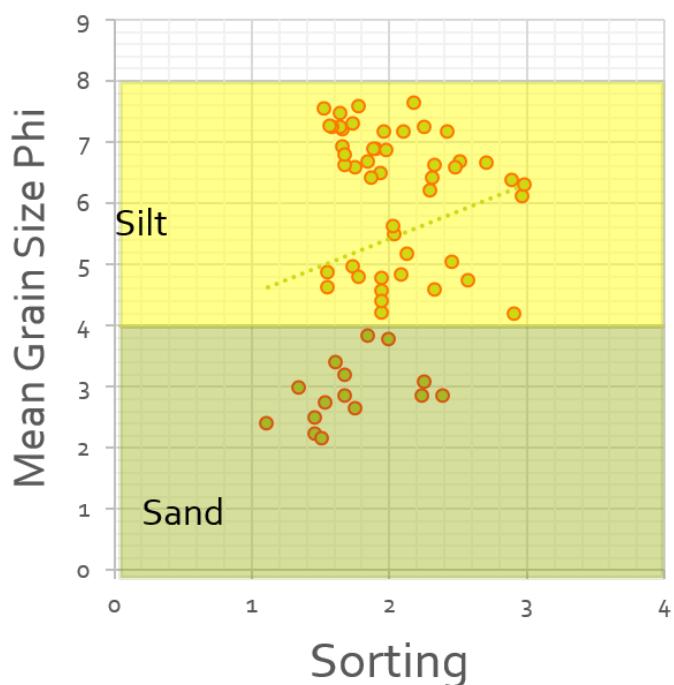

Figure 25. Sorting compared with mean grain size for NRF 15 and USGS 142. The higher the sorting value the more poorly sorted the deposit. The dashed line is a best fit line (R^2 value of 0.0485) and shows very little correlation across all sorting values.

3.5.2 Skewness

$$\text{Equation used (Tucker, 2001)} \quad SK = \frac{\Phi_{16} + \Phi_{84} - 2\Phi_{50}}{2(\Phi_{84} - \Phi_{16})} + \frac{\Phi_5 + \Phi_{95} - 2\Phi_{50}}{2(\Phi_{95} - \Phi_5)}$$

Two distinct populations are evident when comparing mean grain size against skewness (Fig. 26). The first population is fine to medium sand (shoreline facies) and is skewed to the fine/positive direction. The next is lake facies and has skewness values close to zero. These two populations show that fines are incorporated more into fine to medium sand samples, and that there is a distinct lack of coarse grained material in sediment interpreted to be deposited in lakes.

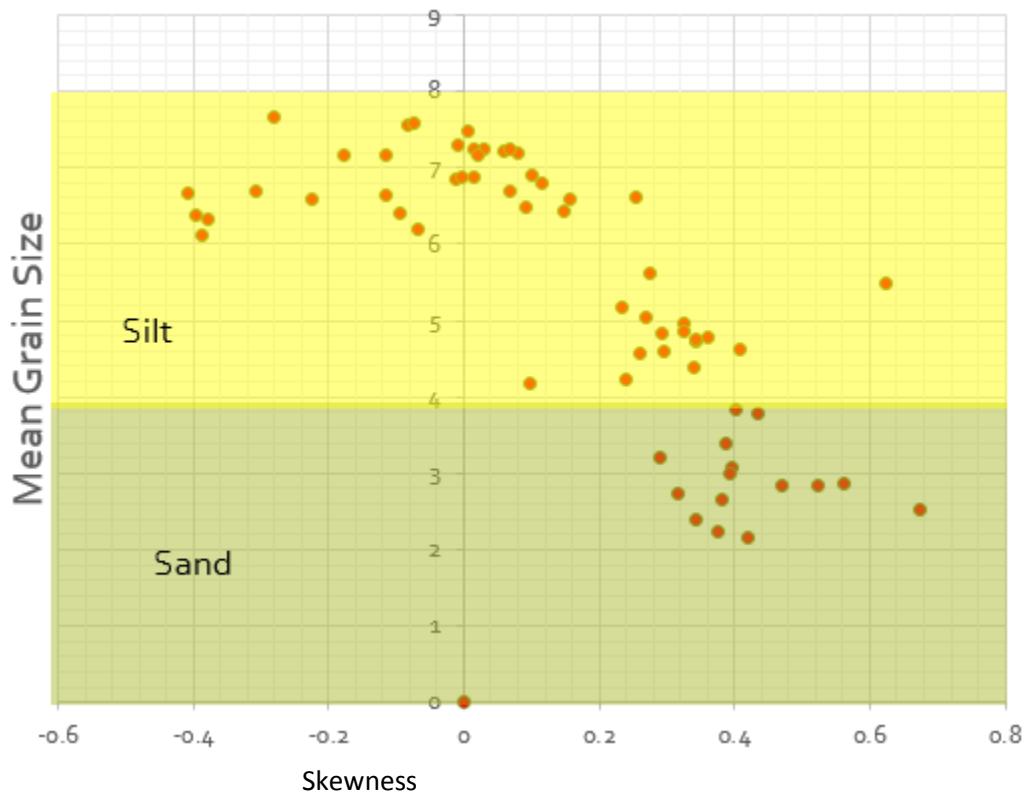

Figure 26. Mean grain size compared to skewness. Positive values are fine skewed while negative values are coarse skewed

3.5.3 Cumulative Frequency Curves

Figure 27 shows the cumulative grain size frequency for all samples collected from USGS 142. Loess deposits, blue, are easily identified as a result of a bi-modal grain size distribution. Green curves represent lake deposits, which are primarily fine grained silt and clay deposits. Yellow represents shoreline deposits, which are dominantly medium to fine sand. USGS 142 has better recovery thus a better representation of the three interpreted facies.

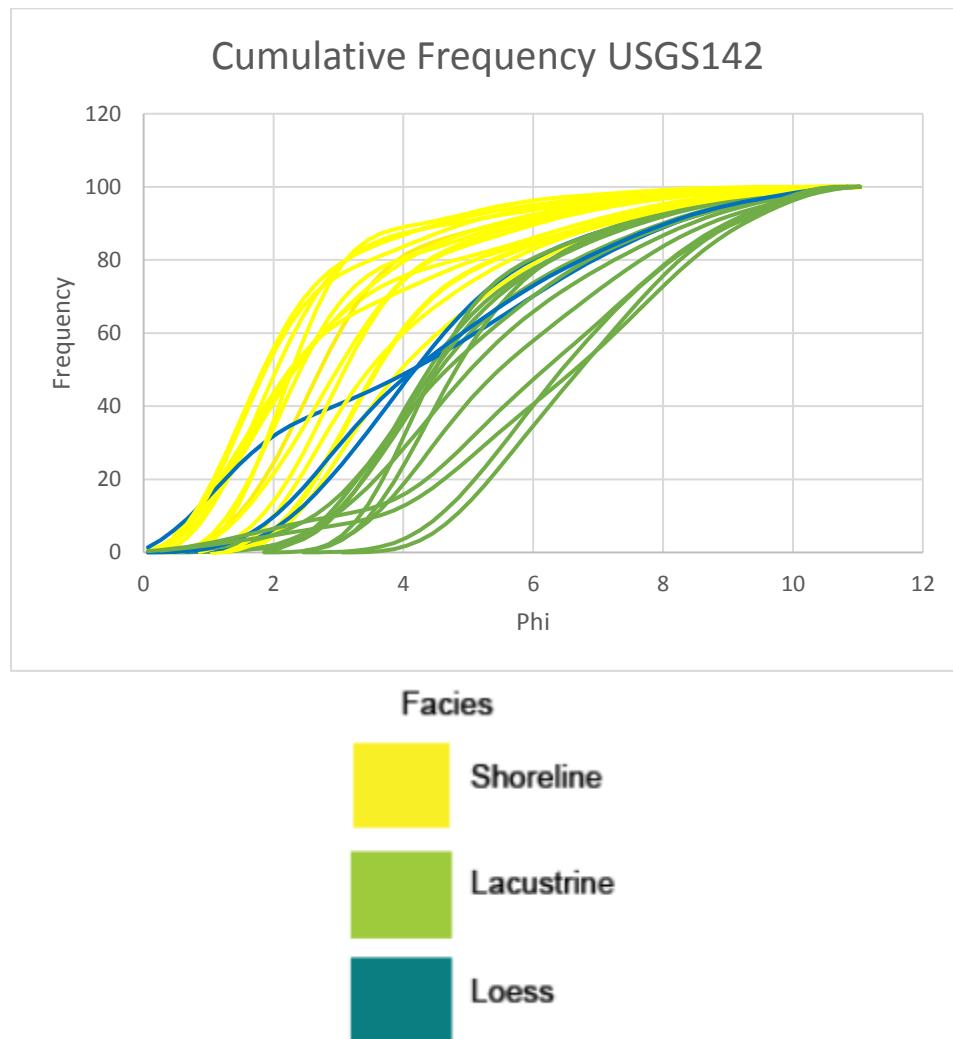

Figure 27: Cumulative frequency of all samples in USGS 142. Note that green is lacustrine, blue is loess and yellow is shoreline.

Figure 28 shows the cumulative grain size frequency for all the samples collected from NRF 15. The green curves shows lake facies, while the yellow represents shoreline, and the blue represents loess. This graph shows a dominance of fine grained material (lake deposits), and small populations of bi-modal and coarse grained material (loess and shoreline). Core recovery is higher in lake facies as deposits are often better cemented compared with coarse grained material, which are lost due to coring techniques.

3.6 Point Counts

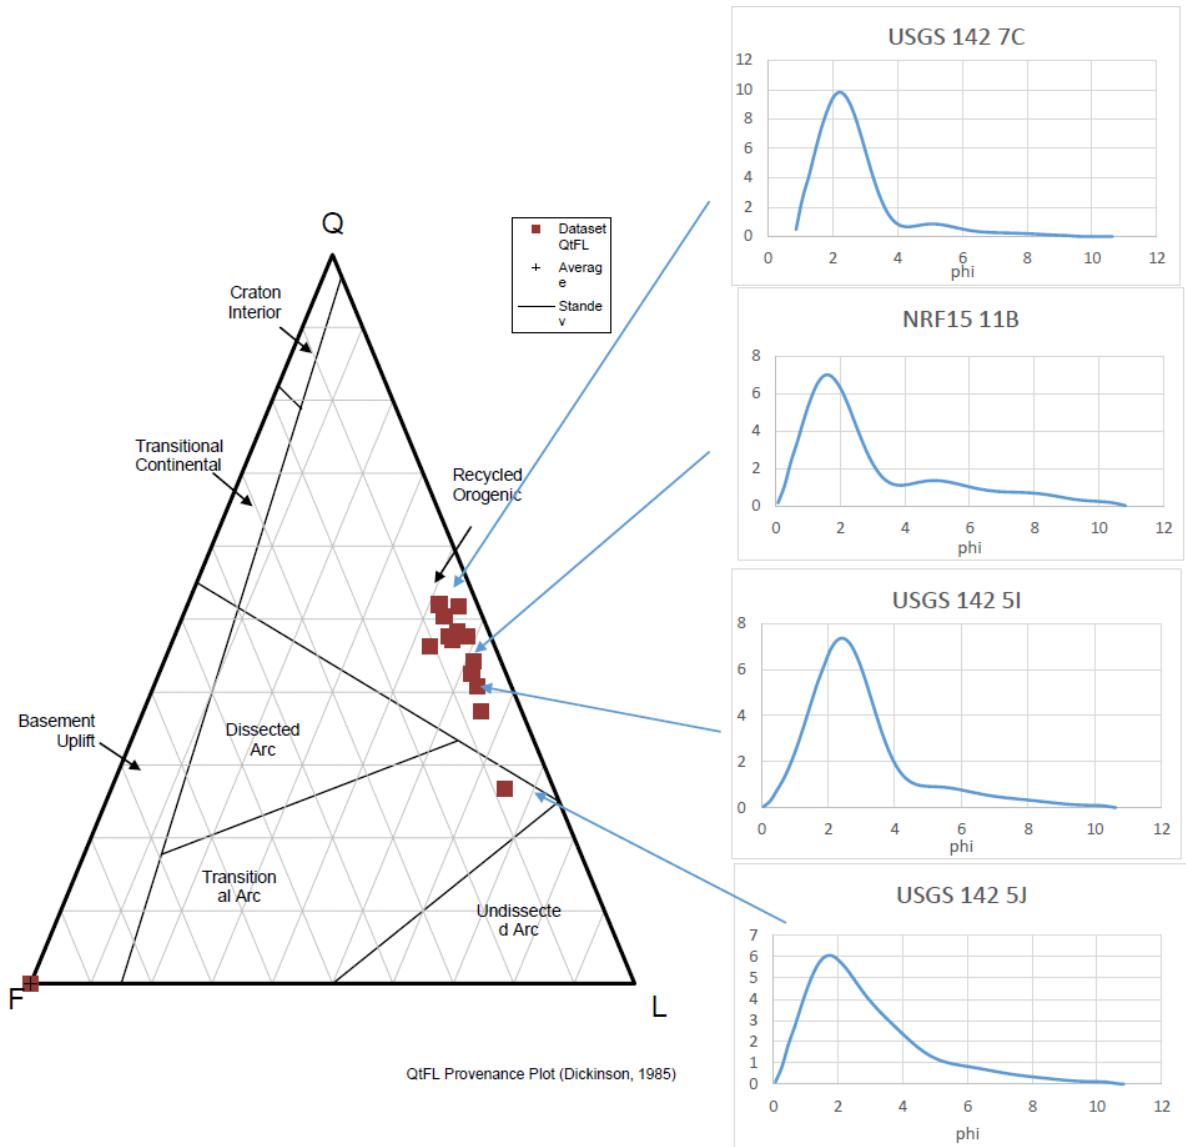

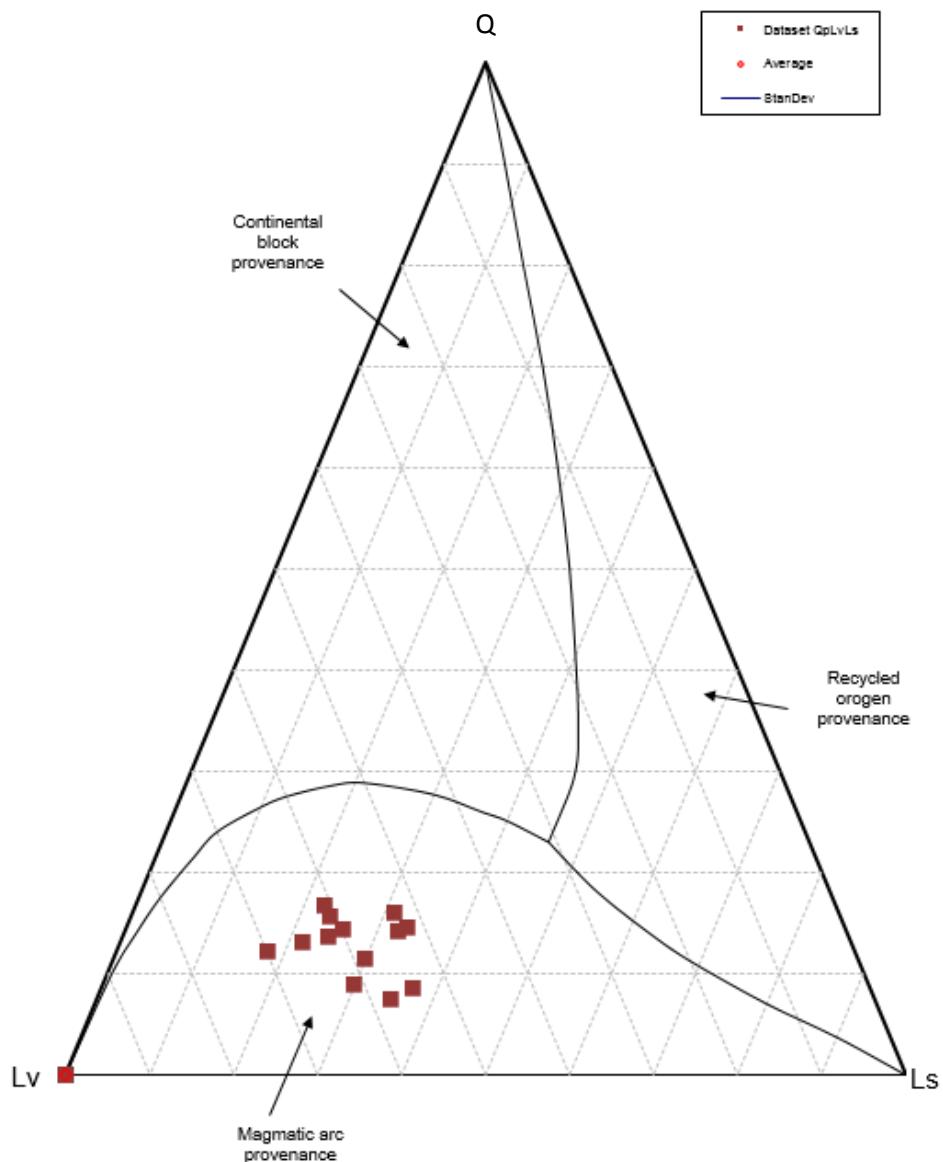

Figure 30: Ternary diagram QFL shows the results of point counting. Graphic grain size distributions on the right.

Figure 30 shows point count results for a series of 13 samples. The samples were chosen based on their lack of cementation, and were thought to represent shoreline facies. The results in the above Quartz-Feldspar-Lithic (QFL) plot show a dominance of quartz and lithics and a distinct lack of feldspars. In these point counts we also see that 58% of the grains are lithics, and of the grains that are lithics 63% are volcanic lithics with 54% of volcanic lithics being felsitic in texture. Grain size distributions show that as the samples become more mineralogically mature,

or contains a larger abundance of quartz, the grain size distributions become more well sorted. As the samples become more well sorted the skewness value becomes lower. Figure 31 shows a predominance of volcanic lithics, and with all samples plotting in the magmatic arc provenance. This means that there is an abundance of volcanic deposits in the region, coming from Challis dacitic volcanics north of the ESRP.

QpLvLs Provenance Plot (Weltje, 2006)

Figure 31: Ternary diagram QLvLs, lithic distributions from point counting.

3.7 Detrital Zircons (Data are presented in appendix E)

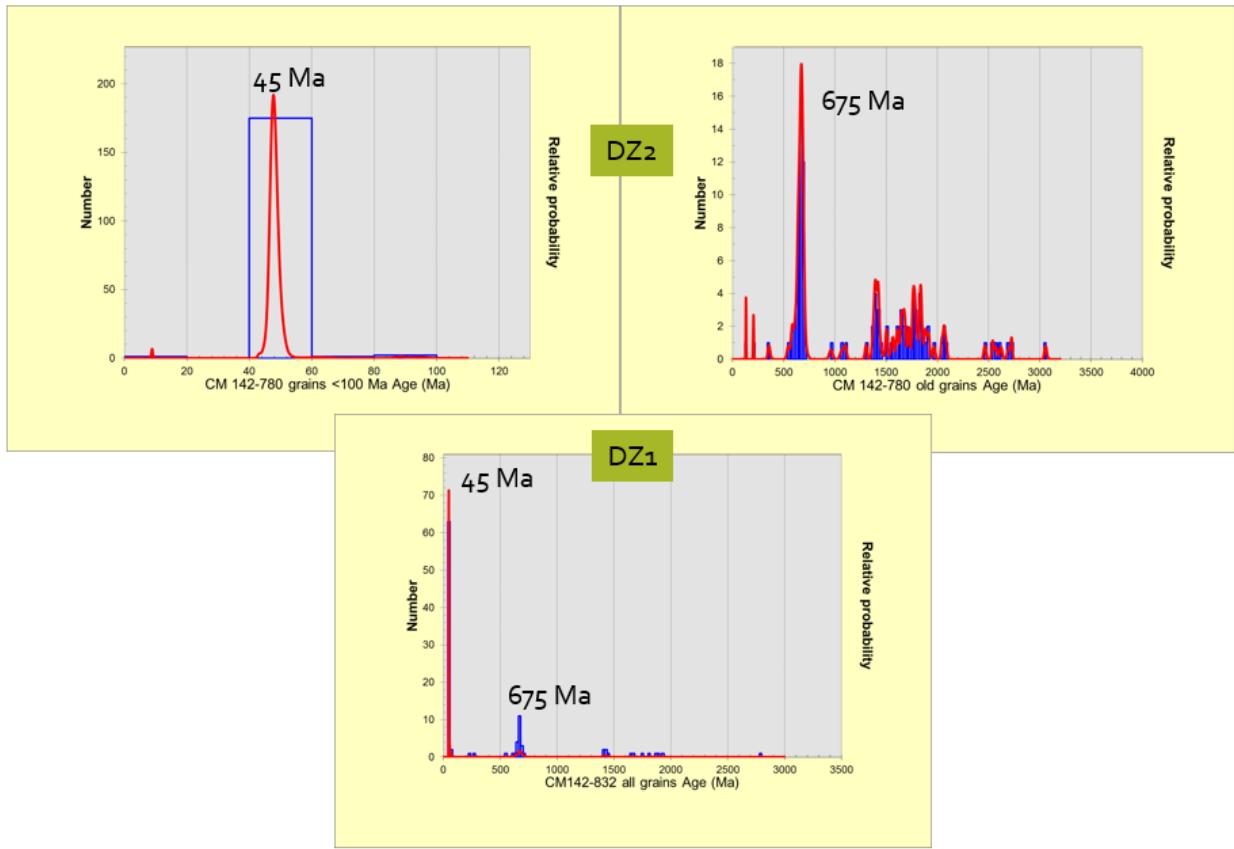

Figure 32: Detrital Zircon age distribution, based on probability density plots for detrital zircon populations of samples DZ1 and DZ2, two prominent peaks are seen in each sample at 45 Ma to 675 Ma, representing sediment sourced from the Challis volcanics and igneous rocks intruded into the Pioneer mountains core complex.

Detrital zircon samples were taken at two stratigraphic intervals in USGS 142. DZ2 was taken at 780 feet BLS while DZ1 was taken at 832 feet BLS (Fig. 32). Both samples weighed roughly two kilograms, and were taken from what we interpreted as shoreline deposits. The above results show two distinct populations. We have a population at 45 Ma and a smaller peak at 675 Ma. Both graphs are very similar in their distribution of zircon grains, and show a source as the paleo Big Lost River, with grains coming from both the Pioneer core complex (675 Ma) and southern Challis volcanics (45 Ma).

3.8 Hydraulic conductivity

Hydraulic conductivity ranges from near zero feet per day to near 12 feet per day (Fig. 33, Table 1, Table 2). This creates a number of zones with little to no conductivity, and also zones with high conductivity. Within each of the correlated intervals, low conductive fine grained silt and clay coarsen up into more conductive fine to medium sands. Non recovered zones could be areas of high conductivity because we assume that these areas are uncemented coarse grained material. In recovered intervals all uncemented material is coarse grained. Though with no grain size values associated with non-recovery zones it is hard to calculate and speculate true grain size and conductivity. Other areas with high conductivity are near the tops and bottoms of lava flows, because these areas are porous and vesiculated (Hodges et al., 2015).

This method does have its limits though. True conductivity values could be off by a magnitude of up to 2, so each sample needs to be considered individually to access true values. Properties that could affect conductivity are sorting and angularity of sediments. With all samples seen in this thesis, sorting ranges from poor to very poor, and sediments are mostly angular. So the hydraulic conductivity given here is probably a good representation of estimated hydraulic conductivity.

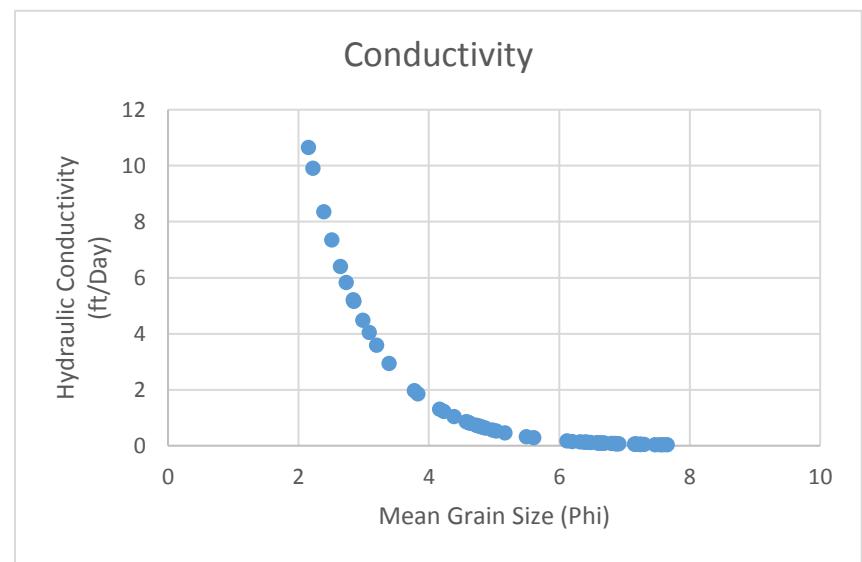

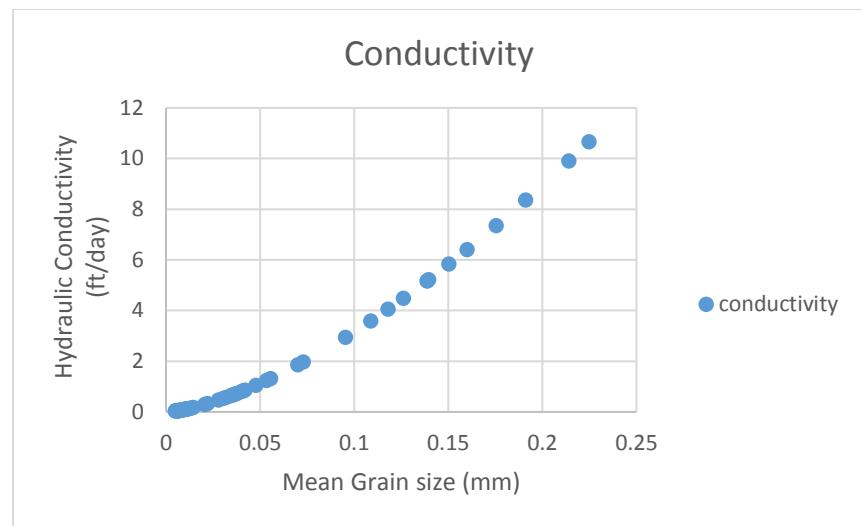

Figure 33: Hydraulic Conductivity and mean grain size. Values range from a few fractions of an inch to upwards of 12 feet per day.

Chapter 4

4.1 Interpretations

4.1.1 Sedimentary Environments

Several depositional environments have been observed on the Snake River Plain (Geslin et al., 1997; Gianniny et al., 1997; Mark and Thackray, 2002; and Bestland et al., 2002). Six surficial facies were described across the BLT by Mark and Thackray (2002): lake floor, playa bottom, dune, loess, channel, and interfluve. In this thesis there are three facies interpretations, lake, shoreline and loess. These three environments are identified based on grain size distribution, skewness, sorting and bioturbation.

As demonstrated here, lake deposits are made up of massive silt and clay and commonly contain rhizoliths (rhizoliths are indicative of shallow lake deposits). Lake facies have a mean grain size of 6 to 8 phi (Mark and Thackray, 2002), are poorly to very poorly sorted, and have symmetrical to slightly coarse skewed grain size distribution. Within lake facies there are commonly lenses of sandy material ranging in thickness from an inch to >3 inches. These lenses are associated with increased sedimentation during flooding events (Benda and Thomas, 1997). In the Pleistocene on the BLT reduced evaporation and more spring runoff created the lake environments present in the cores, and on the ESRP (Pierce et al., 1982; Gianniny et al., 1997; Gianniny et al., 2002).

Shoreline facies are defined by silty sand that overlies lake facies. The transition is gradational between shoreline and lake sediments. Characteristics of the shoreline facies include a mean grain size of 2.5 to 3.5 phi (fine to medium sand), poor sorting, and strongly fine skewed grain size distribution. This increase in medium to fine sand is likely a result of sediment coming out of the paleo Big Lost River (Gianniny et al., 1997).

The loess facies is sparse compared with lake and shoreline, and has a unique bi-modal grainsize distribution. Characteristics of loess include grain sizes from 3-5.5 phi (silt to clay), grain size distribution that is skewed to the fine, and poor to very poor sorting. A bi-modal distribution reflects equal parts sand and silty clay. These sediments are derived from glacial erosional processes, and subsequent eolian reworking (Lewis and Fosberg, 1982; Sun et al., 2004). The fine fraction created from eolian reworking represents entrainment of silt and clay in upper atmosphere winds. The silt and clay then settles out during decreases in wind strengths (Sun et al., 2004). Loess is indicative of glacial climates across the INL, and shows how sediment gets redistribute in the Eastern Snake River Plain region (Forman et al., 1993).

4.1.2 Cyclicity

Cyclicity of sediment facies is seen in both cores NRF 15 and USGS 142 (Fig. 20-Fig.24). The cycle has at its base, a 6-9 foot thick lake deposit that gradually coarsens up, shallowing into shoreline deposits, and in some cases loess. The cycle repeats itself as accommodation space is created through either subsidence (Wetmore, 1998), and a change in lake base level. Sediment deposition moves to a new low. Lakes form, then are overrun by shorelines and then a basaltic event fills in the low. The depocenter migrates as sediment is drawn to a new location in the BLT. Lakes and the related sediment are found as thin units deposited during volcanic quiescence in the BLT during the last 988 ka (Bestland et al., 2002), thus cores are dominated by basalt. This is seen in Fig. 3, Fig. 7, Fig. 34A and Fig. 34B.

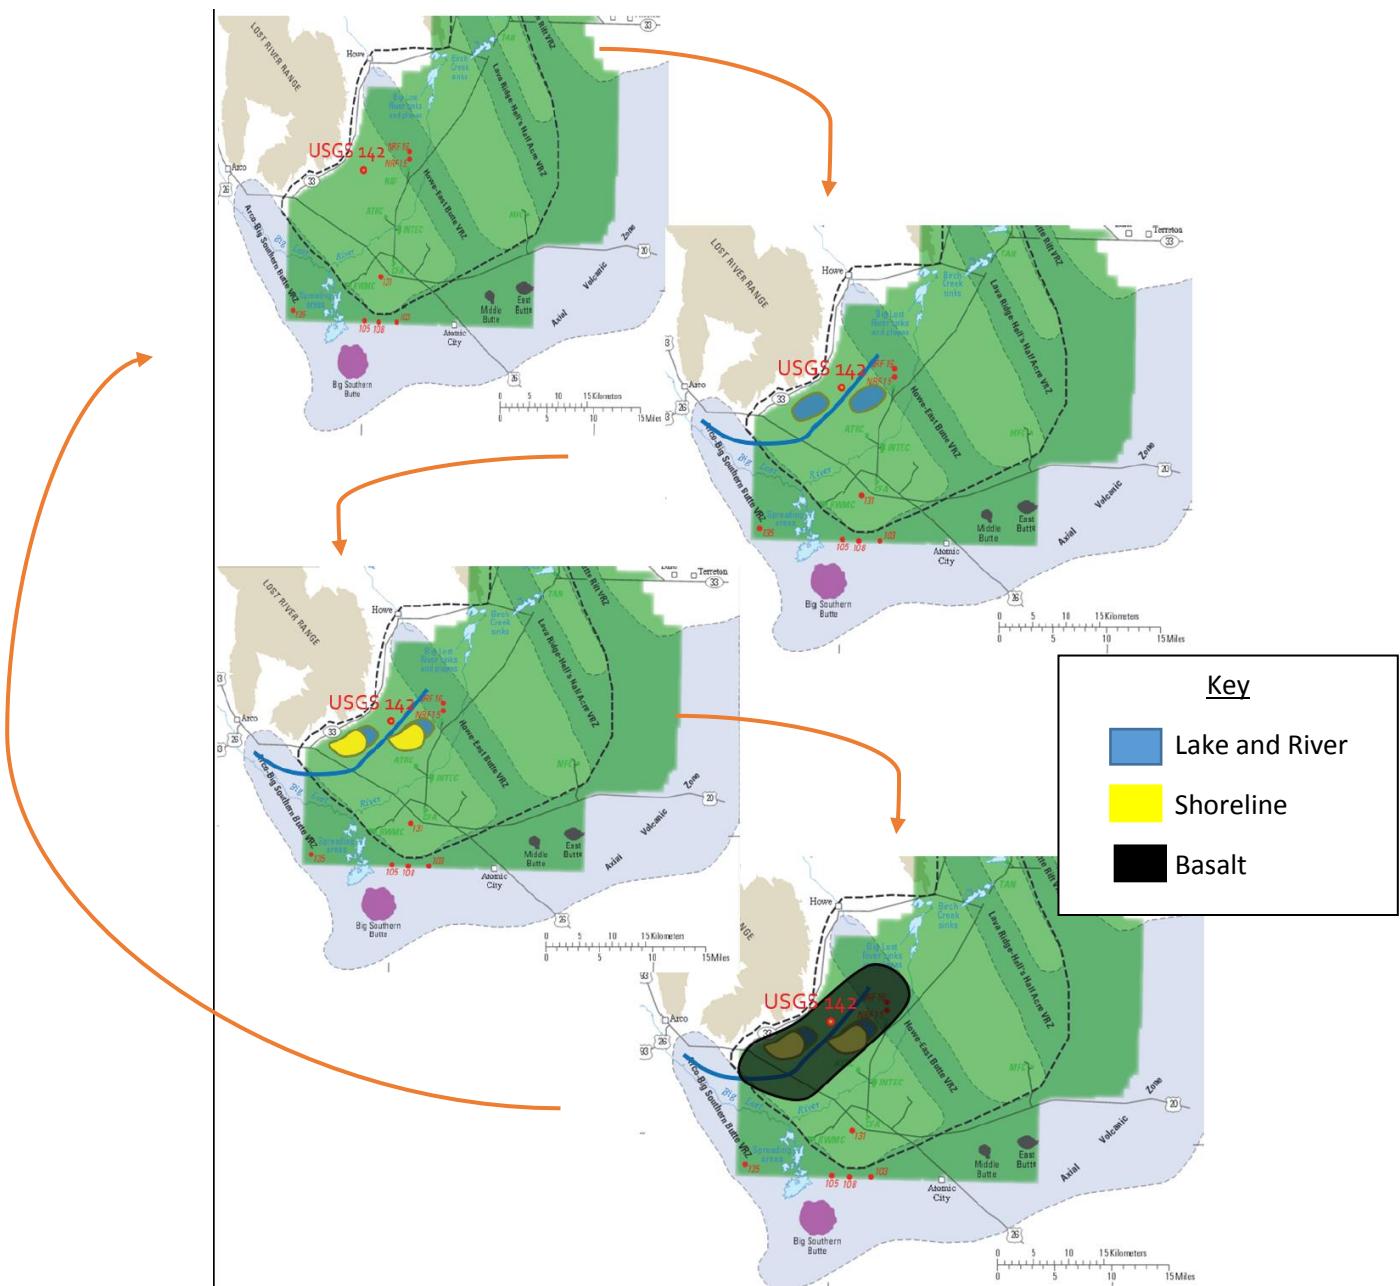

Figure 34A: Sedimentary and basaltic effusive cyclic evolution of the BLT, blue represents lakes and rivers, yellow is shoreline deposits and black is basaltic effusive material, green is the extent of the INL, and grey is both our axial volcanic zone and volcanic rift zones.

Evolution of sediment deposits on the Big Lost Trough

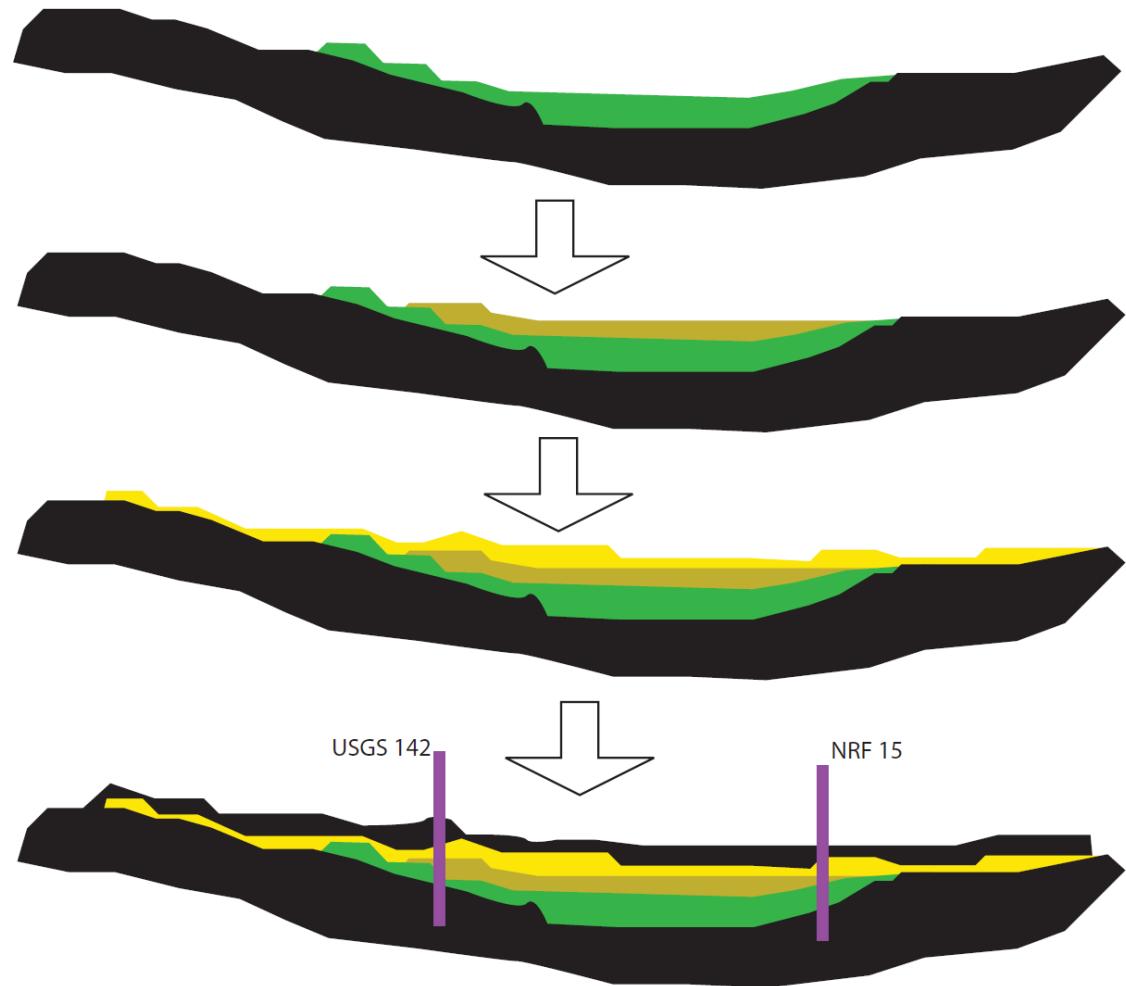

Figure 34B: This shows the evolution of the Big Lost Trough. The environments described shift from lake to shoreline to loess, infilled with basaltic volcanic material, and then subsidence, change in climate, or base level change allows for the cycle to repeat.

4.1.3 Inferred relationships with climatic cyclicity

As much as one hundred thousand years of deposits (884 ka to 988 ka) are represented in the three correlative units found in NRF 15 and USGS 142. This time span is based on paleomagnetic and age constraints on basalt and the sediments themselves could represent less than one hundred thousand years. This time span is correlative to Marine Isotope Stages (MIS) 22-25, two complete glacial to interglacial cycles (Lisiecki and Raymo, 2005). Loess deposition on the ESRP represents glaciation (Lewis and Fosberg, 1982; Pierce et al., 1982; Forman et al., 1993). Cyclicity is made up of cold wet periods or cold arid conditions (glacial) that transition into the modern analog, then back into glacial conditions (Fig. 35 and Fig. 36).

4.1.4 Recurrence intervals

There are 33 identified basaltic flows in USGS 142. If the bottom of the core is 840 ft BSL and is dated 1.045 Ma (Jaramillo). There is an average of one flow per 31 thousand years at the core scale, and each flow is on average 25 ft thick. More accurately, the recurrence interval is longer than this because of multiple flows per basaltic event, and ranges from 30 ka to 150 ka. This gives long periods of volcanic quiescence. Maximum subsidence on the core hole scale is 1 ft per 1.2 ka, calculated from the depth of material deposited and number of years that have passed during that deposition.

During periods of decreased volcanism or quiescence, sedimentation increases across the BLT. The correlated sediment in this thesis spans glacial-interglacial cycles (884ka-1.045 Ma, MIS 22-25). If each glacial cycle is 50 ka (Lisiecki and Raymo, 2005) then we may see sediment corresponding to two to three cycles in core. The accommodation space for sediment is first created by cycles of volcanic damning on long time scales, then rapid climate change represents cycles on shorter time scales. The BLT being a flat low relief surface means that a slight shift in regional climate can cause lakes to dry up into playas and provide space for loess deposition, then

this surface fills with water as the climate becomes wetter. In the sediment presented in this thesis there are two interbeds of loess. This may reflect two glacial interglacial cycle.

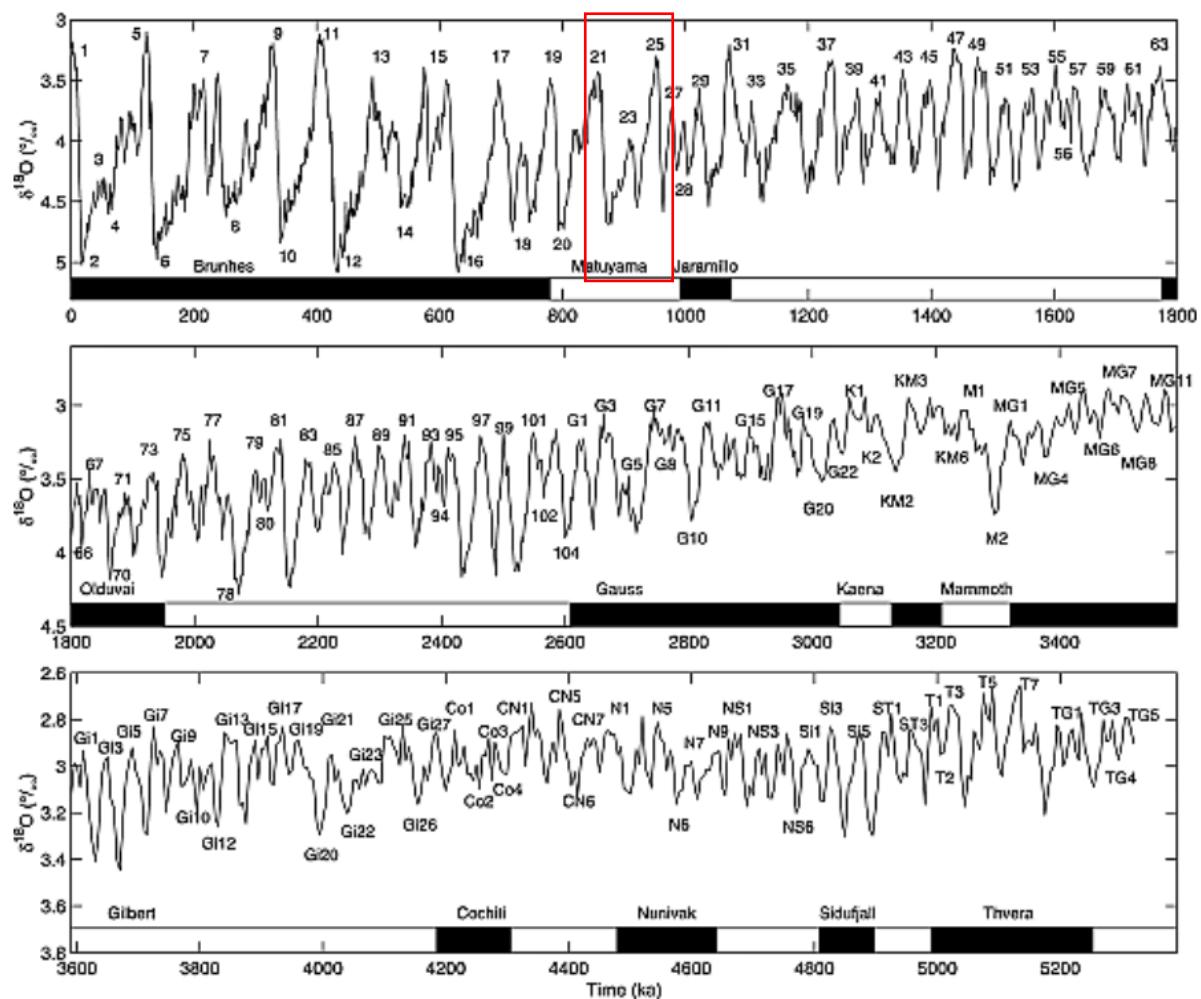

Figure 35: Marine Isotope Stages, defining glacial periods even numbers, and interglacial periods odd numbers, represented by increases and decreases, respectively, in the isotopic record of oxygen ($\delta^{18}\text{O}$), our sediment matches up with MIS 22 -25 (From Lisicki and Raymo, 2005).

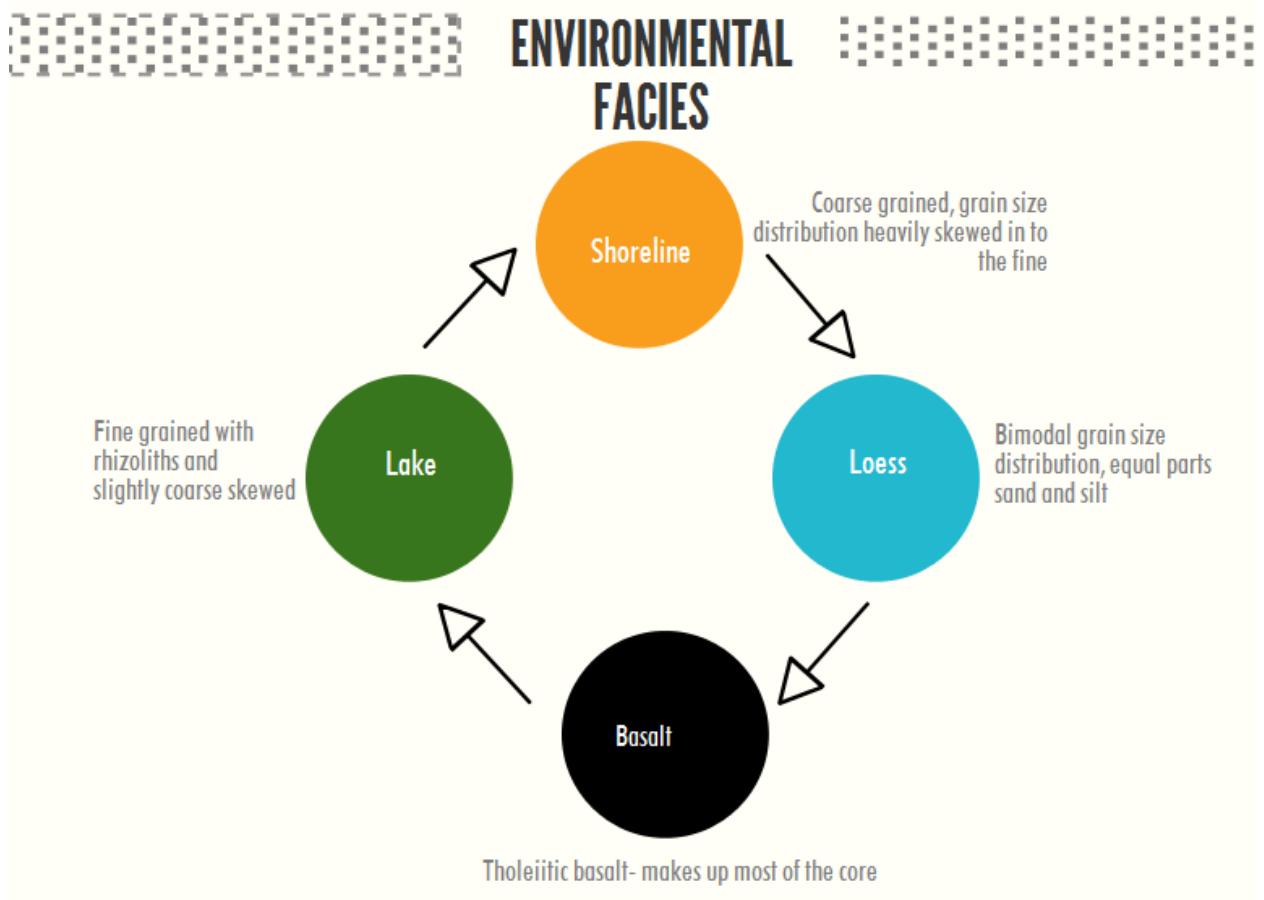

Figure 36: Evolution of cyclic facies across the Big Lost Trough.

4.1.5 Provenance

As seen in both DZ analysis and point counting, samples are dominated by volcanic lithics; more precisely an abundance of felsitic volcanic lithics. Felsitic volcanic lithics are sourced from the Challis volcanics in the region. Extensive areas of Challis volcanic material are found just north and west of the BLT, where the dominant extrusive rock type is dacitic to ryhol-dacitic in composition. This inference is supported by the other major DZ population, which is 675 Ma, the only known source of that age is an orthogneiss in the Pioneer Mountains metamorphic core complex at the source of the Big Lost River (Link et al., 2005). This indicates sedimentation into the western BLT, during MIS 22-25, is dominated by the paleo Big Lost River.

4.1.6 Hydraulic conductivity values reveal a number of confining units within the correlated sediment zone identified in NRF 15 and USGS 142. These aquitards are defined as fine to medium sand that are highly conductive intervals on top of low conductive silt and clay intervals. A good example of a possible confining unit is USGS 142 interval 7E to 7H. USGS 142 7A to 7C have a conductivity ranging from 7.36 feet per day to 10.66 feet per day. These deposits are above samples, USGS 142 7E to 7H, having a conductivity of 0.085 to 0.837 feet per day.

Differential subsidence between NRF 15 and USGS 142 in the last 1.045 Ma is at least 100 ft. This is seen by the depth difference between the three sediment intervals in the two core holes presented in this thesis.

Chapter 5

5.1 Discussion and Implication

Environment cyclicity of facies identified in core, tells a story of landscape evolution. This evolution is portrayed by changes in depositional environments across the BLT. Environments shift through time from basalt to lake to shoreline to loess and back to basalt, and then the cycle repeats. Currently on the INL there are dry playas and sinks, dunes, and loess, with mainly eolian sediment reworking during arid episodes, superimposed on lacustrine and high energy fluvial deposits that were deposited during the last glaciation.

The age of sediment intervals in USGS 142 and NRF 15 is interpreted to lie between 884 ka to 988 ka (north late Matuyama to Jaramillo). This time interval is interpreted to coincide with Marine Isotope Stage 22 through 25 (Lisiecki and Raymo, 2005) (Fig. 35.). This time period spans two glacial interglacial cycles with a maximum time span of 104 ka. These glacial periods might be correlated to wet lake dominated environments, as well as loess deposition.

Detrital zircon analysis show a definite Big Lost River signature. This signature is dominated by a 45 Ma peak, correlating closely with Challis volcanic deposits seen in the proximal mountains north and west of the INL and the BLT. There is also a 675 Ma peak seen in the detrital zircon data, this shows zircons sourced from an orthogneiss in the Pioneer Metamorphic Core Complex, which is exposed in the headwaters or source of the Big Lost River (Link et al., 2005). This signature shows that fluvial material from the paleo Big Lost River was deposited into the Big Lost Trough creating playas and sinks that evolve in to loess and windblown sediment, and are ultimately overrun by effusive basaltic material.

Point counting reveals that 58% of grains are lithics with 63% of those being volcanic lithics and 54% of volcanic lithics being felsitic. The Challis volcanic deposits in the region are dacitic and rhyodacitic in composition. This indicates that volcanic grains in the BLT are coming from the proximal Challis volcanics. Point counting shows us that more mineralologically mature

samples or the more quartz in the sample the tighter the grain size distribution peak. This in turn shows the effect of sediment reworking on grain size distribution.

This project contributes to further understanding of the subsurface of the Snake River Plain. The knowledge of hydraulic conductivity can identify fast paths or aquitards. Grain size helps to identify depositional environments, and allows hydraulic conductivity calculations. Detrital zircon and point counting show a paleo Big Lost River signature.
